PREFACE

This encyclopedia provides the largest integrated reference source of immunological knowledge that is available. In the six years since the first edition of the Encyclopedia of Immunology was published, there have been astounding advances in many areas of the subject. The second edition of the encyclopedia seeks to encompass these advances and to provide a more up-to-date coverage of the subject as a whole than is now provided by the original text. The large number of the topics covered will be of direct interest not only to experimental and clinical immunologists but also to scientists from many other disciplines, including microbiologists, veterinary surgeons, protein chemists, physiologists, hematologists, and so forth. In addition to being a primary reference source, the encyclopedic format readily lends itself to casual reading with most entries being only two or three pages long.

The encyclopedia has been expanded to four volumes, with entries given in alphabetic order; Volume 1 covers ABO Blood Group System to Cooperation, Mechanisms of Cellular; Volume 2 covers Copper and the Immune System to Idiotype Network; Volume 3 covers $I\alpha/I\beta$ (CD79a/CD79b) to Nude (Athymic) Mice; Volume 4 covers Nutrition and the Immune System to Zinc and the Immune System. A complete list of entries is given at the beginning of each volume. Any topic that does not have its own separate entry will be quickly located by reference to the index.

The vast majority of the articles have been totally rewritten from those that appeared in the first edition and the overall production time of the Encyclopedia has been speeded up in an attempt to make the work as current as possible. To reflect important advances there are 64 completely new entries. These cover fields such as second signals for lymphocyte activation, apoptosis, anergy, dendritic cells, nucleic acid immunization, MHC-peptide binding specificity, bacteriophage display of antibody fragments and humanization of antibodies. All areas that were in their infancy when the first edition was produced, but are now central to immunology. Other entries reflect the fact that many cytokines and cell surface molecules have been discovered in the intervening six years. Individual entries are contributed by researchers widely acknowledged as experts in their field. There are a total of 630 entries, and 1200 authors have contributed to this work. Because each entry has been written to be self-contained it would be impossible for there not to be some repetition between entries. Whilst this has in most cases been kept to a minimum, we make no apologies for such overlap as it is felt that the alternative would require the irritating practice of having to flick back and forth between several different entries for the uninitiated reader to fully interpret a particular entry. Inevitably, size limitations have not permitted each entry to be exhaustive; entire books could (and have!) been written with titles similar to individual entry headings. Rather, the aim has been to provide the most pertinent information for each topic. The space allocation imposed upon each contributor has also meant that contributors have not been able to cite by name the work of every individual who has made a significant contribution to their field, but rather they have tried to provide the essential core of the available data.

Readers should note that whilst convention dictates that genes are identified using italicized characters and their protein products referred to using plain text, we have generally only adopted this procedure in entries dealing with nomenclature. Otherwise we have stayed with the approach used by the majority of the contributors, namely using plain text also for the genes whilst making it clear that it is the gene that is being referred to.

The reader will find a list of further reading at the end of each entry, comprising a selection of review articles and perhaps some key papers in each area. Furthermore, at the end of each article there is a cross-referencing '*See also*' section where the reader is directed to other entries within the encyclopedia which contain additional and/or related information.

We have introduced color plate sections into the second edition, not only to add to the attractiveness of these volumes but also to present information, such as computer generated images derived from X-ray crystallographic data, that is otherwise difficult to visualize. Also new for the Second Edition is a glossary providing concise definitions of commonly encountered immunological terms.

An electronic version of the Encyclopedia is available online to purchasers of the print edition (see page iii) which will add to the value of this edition. The user of the electronic version will enjoy extensive hypertext linking and advanced search tools.

We have ourselves, as the first individuals able to consult the completed work, again found it extremely useful as a reference source, a teaching aid, and a text for general interest. We trust others will find this Second Edition of the Encyclopedia of Immunology equally valuable.

April 1998

ACKNOWLEDGEMENTS

The major credit for these volumes clearly rests with the authors of each entry. They are all recognized as being amongst those pre-eminent in their field. We wish to thank each of these authors for their excellent contribution and for their willingness to produce entries to tight deadlines. An additional 'thank you' is also due to the many contributors who provided suggestions and constructive criticism regarding the encyclopedia.

Our task as editors was helped immeasurably by the participation of our outstanding Editorial Advisory Board. Their ability to 'name names', their comments regarding additions or modifications to the list of entries and their expert reviewing of manuscripts established a solid foundation upon which the encyclopedia could be built. We would particularly like to welcome Ian McConnell, Fritz Melchers, Fred Rosen, Emil Unanue and Harald von Boehmer to the Editorial Advisory Board for the second edition of the Encyclopedia.

We greatly thank the following members of Academic Press for the publishing services of editorial development support and production of both print and electronic versions:

Carey Chapman, Lorraine Parry, Sara Gorman, Heather Burroughs, Manjula Kariyawasam, Ed Pentz, Emma Parkinson, Helen Knapp, Debi Kruse, Peter Lord, and also to picture researcher Emma Krikler and indexer Jan Ross.

Finally, thanks to Jane, Joe, Tom and Jess for the inevitable sacrifices that they had to make during the preparation of this second edition of the encyclopedia.

Plate 1

Plate 1 Lymph node. (A) Section of mouse lymph node showing recirculating IgD^+ B cells around their portal of entry. The high endothelial venules (H) located in the T zone (T) are stained blue. IgD^+ cells are also seen in the walls of the intranodal lymphatics on the edge of the T zone and in the follicles (F). En route to the follicles recirculating B cells travel along the walls of the intranodal lymphatics (arrows) where encounter with antigen from the lymph may occur. (B) Section of a formalin-fixed rat lymph node demonstrating large numbers of plasma cells in the medullary cords (M). These are stained brown with anti-Ig. Formalin-fixation has destroyed the surface Ig on the B cells. T - T zone; F - follicle; E - efferent lymphatic. (Kindly provided by Ian MacLennan, University of Birmingham Medical School, UK. Reproduced from MacLennan et al., 1997, *Immunological Reviews* **156**, 53-66 with permission.)

Plate 2

Plate 2 Bone marrow. Trephine biopsy from a 45 year old man (Haematoxylin and eosin stain) Trephine biopsy examination of bone marrow is used commonly to diagnose both hematological and nonhematological conditions. (Kindly provided by Michael Watts, University college Hospitals, London, UK with permission.)

Plate 3

Plate 3 Lymphocyte, neutrophil and monocyte. Bottom left is a small lymphocyte, center is a polymorphonuclear neutrophil and top right is a monocyte showing the characteristic 'horseshoe-shaped' nucleus and moderately abundant pale cytoplasm. Two additional neutrophils are partly in the field of view at the top right. Romanowsky stain. (Kindly provided by the Michael Watts, University College Hospitals, London, UK with permission.)

Plate 4

Plate 4 Tonsil. Section of a normal human palatine tonsil. At upper right (pink) is the stratified squamous epithelium of the surface of the tonsil. This epithelium is highly folded. Beneath it is a collagen fiber layer (blue). At lower center is the lymphoid tissue (red). Apart from the pair of palatine tonsils, there is a pair of lingual tonsils and a pair of pharyngeal tonsils (adenoids) which contribute to the Waldeyer's ring of lymphoid tissue. (With permission from Photo Science Library.)

Plate 5

Plate 5 Antibody binding to a hapten. Stereo view of the 40-50 antibody combining site with V_L on the left and V_H on the right and colored to display concave (dark gray) and convex (green) molecular surfaces. The 40-50 binding site is a groove mostly on the surface of the light chain. The bound hapten, ouabain, is shown in yellow. (Kindly provided by Steven Sheriff, Bristol-Myers Squibb Pharmaceuticals Research Institute, Princeton, USA. Reproduced from Jeffrey *et al.*, 1995, *Journal of Molecular Biology* **248**, 344-360 with permission.)

Plate 6

Plate 6 Antibody paratope. (A) Stereo diagram of a ribbon structure of the $V_H: V_L$ domain showing the side-chains of the contact residues that comprise the paratope of the N10 anti-Staphylococcal nuclease antibody. The heavy chain is colored green, the light chain yellow, CDR regions silver and contact residues (with side-chains shown) are magenta. Figure produced with RIBBONS (Carson 1991). (B) Contact molecular surface (cyan dots) of the N10 antibody (blue with contact residues in yellow) calculated by the method of Connolly (1983) and displayed using GRASP (Nicholls et al 1991.) Note the U-shape of the contact surface with the single heavy chain CDR3 contact residue Asn H-96 located just inside the open end of the U. (C) The N10 antibody paratope with the light chain on the left. Surface representation of the calculated ΔG residue contribution to binding by the N10 antibody and the Staphylococcal nuclease antigen residues. A color scale was constructed of the ΔG residue values, from blue (-2.0 kcal/mol) to red ($+2.0$ kcal/mol). Thus, blue colors represent negative ("attractive") residue contributions, red colors represent positive ("repulsive") contributions. Figure produced with GRASP (Nicholls et al 1991). (Kindly provided by Steven Sheriff, Bristol-Myers Squibb Pharmaceuticals Research institute, Princeton, USA. Reproduced from Bossart-Whitaker *et al.*, 1995, *Journal of Molecular Biology* **253**, 559-575 with permission.)

Plate 7

A

B

Plate 7 (A) Addison's Disease. Adrenal gland from patient with Addison's disease, showing atrophy of the cortex and infiltration with mononuclear cells. (B) Another area from same adrenal gland, photographed at higher magnification. (Kindly provided by P E Bigazzi, University of Connecticut Health Center, USA with permission.)

Plate 8

Plate 8 Allergens. Molecular modeling of the cockroach calycin allergen, Bla g 4. The C α backbone structures for two models of Bla g 4 (designated bg12A-1 and bg12A-2) were modeled on the X-ray crystal coordinates for butterfly bilin-binding protein (BBP) and are compared with rat urinary protein allergen (RUP), for which the X-ray crystal structure has also been determined. The yellow spheres are conserved amino acid residues that form motifs which define the ligand-binding proteins, or calycins. (Kindly provided by M D Chapman, University of Virginia, USA with permission.)

Plate 9

Plate 9 Antibody-antigen interaction. (A) Conformational differences in antibody D1.3 V_L CDR3 induced by differing antigen side-chains. Hen egg lysozyme (HEL) residue Gln121 makes two main-chain hydrogen bonds; to the carbonyl oxygen of D1.3 V_L Phe91 and the amide nitrogen of D1.3 V_L Ser93. Replacement of the glutamine by histidine in Turkey egg lysozyme (TEL) induces a conformational change in the backbone of V_L CDR3 which allows the formation of a hydrogen bond between the histidine and the carbonyl oxygen of V_L Trp92. (B) The effect of a Trp-Asp mutation on the interaction surface area of the D1.3-HEL complex (dots) and the mutant D1.3-HEL surface (solid line) demonstrates the loss of interaction surface area in the mutant complex. A 150 Å² loss in surface area accounts for the reduction in affinity of the mutant D1.3-HEL reaction. (C) Hydrogen bonding network of the D1.3-HEL interface mediated by bound solvent molecules; 25 water molecules form hydrogen bonds linking the antibody and antigen, directly or through other water molecules. (D) Water molecules in contact with the D1.3-HEL buried surface. Including the 25 bridging water molecules, nearly 50 solvent sites are in contact with the buried surface defined by the D1.3-HEL interface. Many of these water molecules fill internal cavities, further stabilizing the complex. (Kindly provided by B C Braden and R J Poljak, Center for Advanced Research in Technology, USA with permission.)

Plate 10

Plate 10 HLA-A2. The residues forming the domain interfaces are highlighted in color on the C_α backbone stereogram. Filled and colored C_α atoms make contacts ≤ 4 Å. Red, α_1 , α_2 residues in interface with β_2M ; green, β_2M residues in interface with $\alpha_1\alpha_2$; blue α_3 residues in interface with β_2M ; yellow, β_2M residues in interface α_3 ; pink, $\alpha_1\alpha_2$ residues in interface with α_3 ; orange, α_3 residues in interface with $\alpha_1\alpha_2$. (A) A view perpendicular to $\alpha_1\alpha_2$ pseudodyad with the binding cleft viewed end-on ($\alpha_1\alpha_2$ - α_3 interface not shown). (B) A side view with the molecule rotated 90° about the pseudodyad (α_3 - β_2M interface not shown). (Reprinted with permission from Saper MA, Bjorkman PJ and Wiley DC (1991) Refined structure of the human histocompatibility antigen HLA-A2 at 2.6 Å resolution. *Journal of Molecular Biology* **219**: 277-319.)

Plate 11

Plate 11 CD8. Three-dimensional molecular model of the N-terminal region of a CD8 homodimer consisting of two α chains; (A) ribbon presentation, (B) stick presentation. The structural data for the N-terminal 113 amino acids are based on crystallography (protein data base: 1CD8). The three-dimensional model for each monomer was generated with RasMol version 2.5 (Roger Sayle, Greenford, Middlesex, UK), and the two monomers were combined as described (Leahy *et al.* (1992) *Cell* **68**: 1145). The color coding represents groups; blue corresponds to the CDR1-like loop, light blue to the CDR2-like loop, and lime to the CDR3-like loop. The monomers are distinguished in brightness of color. (Kindly provided by GF Weber and H Cantor, Dana-Faber Cancer Institute, USA with permission.)

Plate 12

Plate 12 Dendritic cell. Colored scanning electron micrograph. (With permission from Photo Science Library.)

Plate 13

Plate 13 Monoclonal antibodies to lysozymes. Hen egg white lysozyme in complex with the Fab fragments of monoclonal antibodies raised against it. An exploded-view collage indicating how three different anti-lysozyme Fab's interact with lysozyme (center) in the x-ray structures of their respective complexes. The proteins are represented by their C_α chains and their interacting surfaces are outlined by juxtaposed dot surfaces. Note that the three crystal structures on which this diagram is based each contain only one Fab species; the Fabs do not crystallize together. (Photograph courtesy of Steven Sheriff and David Davies, NIH, USA.)

Plate 14

Plate 14 High endothelial venules in lymph node. (A) Rat mesenteric lymph node. Composite of about 200 scanning electron micrograph images. The capsule and the marginal sinus (MS) are seen at the top. The high endothelial venules (HEVs) are distributed mainly in the inner cortex and further in the interfollicular areas. The lymphatic labyrinths filled with lymphocytes are demonstrated in the inner cortex. S. medullary sinus. The lymphatic labyrinths and medullary sinuses are tinged in pale and dark blue, respectively. (B) Fractured portion of the inner cortex. An HEV is longitudinally opened at the lower left. The lymphatic labyrinth (L.L.) is shown near the HEV. (Kindly provided by Yechen He, Harbin Medical University, China, with permission.)

Plate 15

Plate 15 Germinal center. (a, b) Follicular T cell numbers rapidly increase during germinal center development. In a non-responding spleen (a) T cells in the white pulp are largely confined to the T zone (T) with only occasional T cells in the follicles (F); red pulp (R). (b) 7 days after primary immunization with antigen large numbers of T cells are found within the developing germinal center and surrounding follicular mantle – up to 10% of these have incorporated the thymidine analogue BrdU during a 2-hour pulse indicating that they are in cell cycle. (c, d) A pulse chase experiment where centroblasts in the dark zone (D) of a rat splenic germinal center are labeled during a 5-hour pulse with BrdU. In panel c the spleen is taken at the end of the pulse when almost all centroblasts are labeled but the majority of centrocytes in the light zone (L) are not labeled. The spleen in d was taken 7 hours later when centrocytes derived from the proliferating centroblasts are labeled. F - follicular mantle; M - marginal zone; T - T zone. (Kindly provided by Ian MacLennan, University of Birmingham Medical School, UK. Reproduced from MacLennan *et al.*, 1997, *Immunological Reviews* **156**, 53-66 with permission.)

Plate 16

Plate 16 Delayed-type hypersensitivity. Brucellosis. Delayed-type hypersensitivity (DTH) reaction in the finger following needlestick injury. When vaccinating cattle, veterinarians are prone to needle stick injury. In those who have been sensitized by previous infection, albeit subclinical, this can be followed within 24-48h by a DTH reaction which ranges from the local reaction shown here, to a severe, generalized response which resembles many aspects of the infection itself. (Photograph courtesy K Hughes and the late J Forbes.)

Plate 17

Wild-Type

LT α -Deficient

Plate 17 Lymphotoxin knockout mice. Absence of germinal centers in mice lacking lymphotoxin α (LT $\alpha^{-/-}$ mice). Wild-type (left panel) and LT $\alpha^{-/-}$ (right panel) mice were immunized intra-peritoneally with 10^8 sheep red blood cells and 10 days later spleen sections were analyzed by staining with the germinal center marker peanut agglutinin (blue) and with anti-IgD (brown). (Kindly provided by David Chaplin, Washington University School of Medicine, USA. Reproduced from Matsumoto, M *et al.* 1997, *Immunological Reviews* **156**, 137-144 with permission.)

Plate 18

A

C

B

Plate 18 Cutaneous anaphylaxis. (A) (*above left*) Acute urticaria with marked erythema and whealing. (B) (*above*) Urticaria showing central clearing and an annular pattern. (C) (*left*) Symptomatic dermographism, marked linear whealing has occurred at sites of scratching. (Kindly provided by MHA Rustin and CH Ortey, The Royal Free Hospital, UK.)

Plate 19

Plate 19 H-2K polymorphism. Ribbon diagrams of the H2-K^b molecule with the vesicular stomatitis virus 8mer (RGYVYQGL) bound. Polymorphic residues in the $\alpha 1$ domain (exon 2) are highlighted in blue, $\alpha 2$ (exon 3) in red, and $\alpha 3$ (exon 4) in purple. (A) T cell receptor view of the complex. (B) (*right*) side view of the molecule. (Kindly provided by JA Frelinger and EJ Collins, University of North Carolina, USA with permission.)

Plate 20

Plate 20 Antibody complementarity determining regions (CDRS). Computer graphic model of the structure of the V_H component of NEWM human antibody. The CDRs loop out from the scaffold structure of the framework regions (blue) to provide the antigen binding surface at one end of the molecule. The framework residues marked are those most commonly involved in maintaining the correct conformation of the CDR loops. (Reproduced with permission from Harris WJ and Cunningham CC (1995) *Antibody Therapeutics*; Austin TX: RG Landes.)

Plate 21

Plate 21 T cells in lymph node. (A) T cells proliferating during the priming process in association with interdigitating dendritic cells (IDC) in the T zone of a lymph node 3 days after immunization with hapten-protein antigen. The proliferating cells are stained red indicating that DNA in their nuclei contain the thymidine analogue BrdU, which was given as a 2 hr pulse before the node was taken. The IDC are identified by their expression of MHC class II molecules stained blue: staining on serial sections for the B-cell associated molecule B220 and CD4 indicates that the proliferating cells are T cells and the class II⁺ cells in contact with them are IDC. (B, C, D) Antigen-specific T cells are maintained long-term during a chronic follicular response in the popliteal lymph node draining the site of infection with murine mammary tumor virus MMTV (SW). Serial sections from the node taken 4 months after infection show a germinal center G stained in panel (B) with PNA (peanut agglutinin). T cells are shown in panel (C) and Vβ6 T cells in panel (D); these are present in the follicular mantle F, germinal center and T zone T. The superantigen-reactive T cells are selectively conserved in the responding node but are depleted from other lymphoid tissues. (Kindly provided by Ian MacLennan, University of Birmingham Medical School, UK. Reproduced from MacLennan I *et al.*, 1997, *Immunological Reviews* **156**, 53-66 with permission.)

Plate 22

Plate 22 Cancer immunotherapy. False-color scanning electron micrograph of two lymphokine-activated killer (LAK) cells. In LAK immunotherapy, a patient's peripheral blood mononuclear cells are removed and cultured with interleukin-2 (IL-2) to allow LAK cells to develop. (With permission from Photo Science Library.)

Plate 23

Plate 23 Lymphatic vessel. Light micrograph of a vessel in the human lymphatic system, showing a one-way valve. The vessel is red; the W-shaped valve (center) allows fluid to pass from right to left, but prevents backflow of lymph. (With permission from Photo Science Library.)

Plate 24

Plate 24 Interleukin-1 receptor (IL-1R). Soluble IL-1R (s-IL1R) complexed to IL-1 β . Left, Ribbon diagram showing domains 1, 2 and 3 of s-IL1R colored light, medium and dark blue, respectively. IL-1 β is yellow, with site A residues in green and site B residues in red. Right, Ribbon diagram with the β -strands shown as arrowed ribbons in green, α -helices in red, and the connecting loops in purple. The structure is oriented so that the carboxy terminus of s-IL1R and the cell membrane, if present, are at the bottom of the picture. (Kindly provided by Guy Vigers, Amgen Inc, Boulder, Colorado, USA. Reproduced from Vigers, G.P.A. *et al. Nature* 1997, **386**, 190-194 with permission.)

Plate 25

Plate 25 Peptide-MHC interaction. Pockets in the HLA-DR1 peptide binding site. Side view of the molecular surface of the HLA-DR1 peptide-binding site with She influenza hemagglutinin peptide 306-318. Peptide side-chains are labeled in one letter code. (Reproduced by copyright permission from Stern, LJ *et al* *Nature* 1994; **368**; 215-221.)

Plate 26

Plate 26 Immunocytochemistry. (A) DAB peroxidase-labeled anti-B lymphocyte antibody in human tonsil tissue. (B) DAB peroxidase-labeled anti-T lymphocyte antibody in human tonsil tissue. (C) Peroxidase-labeled anti-S100 antigen antibody in a skin sample. (D) AEC peroxidase-labeled anti-cytomegalovirus antibody in reproductive tract. (E) Antibody against factor VIII-vWB antigen labeled with AEC peroxidase. (F) DAB peroxidase labeled antidesmin in human muscle tissue. (G) Anti-EMA antigen in a case of cervical cancer. (H) Antibodies against vimentin in a human sarcoma tissue. (I) Anti-AE1/AE3 (cytokeratin) antibody labeled with AEC peroxidase in human tissue. (Kindly provided by CD MacKenzie, Environmental Pathobiology Laboratory, USA, with permission.)

Plate 27

Plate 27 An 'antigen's eye view' of sequence diversity in human antibodies. Sequence diversity is plotted on a scale of blue (more conserved) to red (more diverse). The V_H domain is to the right and the V_L domain is to the left of each representation. (A) Germline diversity is focused at the center of the antigen binding site. (B) Somatic hypermutation spreads diversity to regions at the periphery of the binding site that are highly conserved in the germline V gene repertoire. Somatic hyper-mutation is therefore complementary to germline diversity. The CDRH3 region was not included in this analysis and is therefore shown in gray. The end of CDRL3 (also excluded) lies at the center of the binding site and is not visible in this representation. (Reproduced with permission from Tomlinson M *et al* (1996) *Journal of Molecular Biology* **256**: 813-817.)

Plate 28

Plate 28 Stat 1 knockout mice. STAT1-deficient mice are extremely susceptible to viral infections. Transcriptional responses to interferons (IFNs) are mediated by tyrosine phosphorylation and nuclear translocation of transcription factors of the signal transducer and activator of transcription (STAT) family. Disruption of the gene for STAT1 in embryonic stem cells and in mice revealed that the STAT1 protein is required for all transcriptional responses to IFN (both type I and type II). STAT1-deficient mice grow and develop similar to wild-type animals, but show compromised innate immunity to viral disease. These animals fail to survive in the presence of otherwise innocuous pathogens, including mouse hepatitis virus. Histological examination of liver tissue from STAT1-deficient animals dying of disease showed multifocal hepatic necrosis with syncytial cell formation (A) and scant inflammatory response, consistent with viral hepatitis (caused by infection with mouse hepatitis virus). Analysis of hepatic tissue taken from wild-type siblings demonstrated no pathology (B) (Photograph courtesy of JE Durbin and DE Levy.)

Plate 29

Plate 29 *Staphylococcus aureus* septicemia. The bacteria may spread as emboli to peripheral vessels. (Kindly provided by Asa Ljungh, Lund University, Sweden.)

Plate 30

Plate 30 Human thymus. The thymus is divided into lobules separated by septa of connective tissue (white spaces) which may contain blood vessels (examples at center and far right). The body of the thymus is divided into an outer cortex (ink blue stain) and inner medulla; the medulla is less densely packed with lymphocytes. The pink, circular features within the medulla are called Hassal's corpuscles, cyst-like structures that may represent degenerated epithelial cells. (With permission from Photo Science Library.)

Plate 31

A

B

C

D

Plate 31 Heat shock protein. Immunofluorescence with monoclonal antibody W27 against heat shock protein (HSP) 70 (A, C) and the DNA-binding fluorescent molecule 4',6-diamidino-2-phenylindole (DAPI) (B, D). Staining of control (A, B) and heat shock activated (C, D) HeLa cells showing HSP 70 nuclear translocation in response to heat shock activation. (Kindly provided by Santa Cruz Biotechnology, Inc. USA, with permission.)

Plate 32

Plate 32 Rheumatoid arthritis. Three-dimensional representation of HLA class II molecule containing the antigenic processed peptide in the antigen-binding groove (light blue stretch, top of the figure). The five amino acid sequence QR/RRAA ('shared epitope') is common among all HLA alleles correlated to rheumatoid arthritis. (Kindly provided by A La Cava and S Albani, University of Carolina, USA, with permission.)

Plate 33

Plate 33 (A) Secretory component (the polymeric Ig receptor). Paired immunofluorescence staining for IgA and SC in tissue section from human nasal mucosa; the same field is shown after incubation with 'red' anti-IgA + 'green' anti-SC, (i) (red filtration) and (ii) (double exposure). IgA alone is present in immunocytes and throughout the stroma; SC alone is present in the Golgi zones (arrows) adjacent to nuclei of glandular acinar cells; both IgA and SC (mixed color) are present basolaterally on acinar cells and apically in their cytoplasm.

Plate 34

Plate 34 (B) Paired immunofluorescence staining for IgA and total SC, or for unoccupied and bound SC, in tissue sections of human colonic mucosa. (i) left part (red filtration) and right part (double exposure), comparable fields in adjacent sections of gland incubated with 'red' anti-SC and with 'red' anti-IgA + 'green' anti-SC, respectively. Prominent SC-containing granules are present in the Golgi zones, whereas the rest of the cytoplasm and the basolateral aspects of columnar epithelial cells are positive for both SC and IgA (mixed color). Goblet cells are devoid of both markers. (ii) (red filtration), (iii) (left part, double exposure), and (iv) (green filtration), same field in a section of gland incubated with 'red' anti-I determinant (specific for unoccupied SC) + 'green' anti-A determinant (accessible on free as well as bound SC). The two antigenic determinants show distinct differential distribution with a relative dominance of I in the Golgi zones, and of A in the remaining cytoplasm and weakly also basolaterally. Right part of (iii) (double exposure) shows a comparable field after prolonged exposure time for red (anti-I) emission. Note that neither of the two anti-SC reagents produced fluorescence of elements in the lamina propria.

Plate 35

Plate 35 (C) (i) Paired immunofluorescence staining to demonstrate *in vitro* SC affinity to IgA immunocytes in section of human colonic mucosa preincubated with free SC followed by 'red' anti-SC + 'green' anti-IgA. Note in double exposure (center) that most IgA cells show varying degree of mixed color as evidence for binding of SC to cytoplasmic polymeric IgA (pIgA), whereas a few cells (probably pure monomer producers) lack SC-binding and are therefore only green. The purely red cells in the double exposure are SC-binding IgM immunocytes. The columnar epithelial cells of the glands at top and bottom contain innate SC and transport pIgA; they therefore show mixed cytoplasmic color with the exception of the Golgi zones which contain SC but no IgA. (ii) Similar SC-affinity test on section of human salivary gland. Double exposure (center) shows various tints of yellow in IgA immunocytes located between acini A and duct D on the figure; in several immunocytes the yellow color is restricted to areas close to the nucleus (arrow), suggesting accumulation of pIgA. One immunocyte (at the bottom) is purely green, suggesting production of only monomeric IgA. Acini and duct are faintly double-stained for unoccupied SC and translocated pIgA. Plate 36

Plate 36 (A) Anti-lysozyme binding site Surface complementarity between the antigen, hen egg-white lysozyme and the antibody HyHEL-5 binding site. In this cross-reaction through the antigen-antibody complex, 5 Å thick, centers of atoms are connected by sticks and atomic volumes are shown as Conolly dot surfaces. Atom color-coding; oxygen, red; nitrogen, blue; sulfur, yellow; carbon in lysozyme, white; carbon in V_L domain, magenta; carbon in V_H domain, brown. The intermolecular interface, approximately traced by a line dividing the antigen atoms (lower part) from those of the antibody (upper part), consists of tightly packed regions, and occasional loosely packed regions, 'cavities'. The intermolecular cavities, for example the one delimited by lysozyme residue Arg 68 and the antibody residues L 91, H 33 and H 35 (blue arrow, on the top), are not any larger, however, than the occasional intramolecular cavities (white arrow, on the bottom). Crystallographic coordinates by Sheriff S *et al.* (1987), *Proceedings of the National Academy of Science of the USA* **84**: 8075-8079, with permission.

Plate 37

Plate 37 (B) Electrostatic fields at the surface of the HyHEL-5 antibody binding site. This monoclonal antibody is specific to lysozyme, a protein with an exceptionally high positive charge. Using the crystallographic coordinates of the HyHEL-5 V_H and V_L domains (Sheriff *et al*, (1987) *Proceedings of the National Academy of Science of the USA* **84**: 8075-8079, with permission.) molecular surface envelope was generated by the program GRASP (A Nicholls, Columbia University 1991) and was color-coded by the electrostatic field produced by all the formally charged residues in the molecule: red, negative potential; blue, positive potential; color intensity proportional to the strength of the field). At the center of the binding site there is a deep, electronegative cavity 'below' which is a protruding side-chain of the Arg residue L93, with a weaker, positive, electrostatic field. In the HyHEL-5-lysozyme complex, the central negatively charged cavity becomes occupied by the two positively charged lysozyme side-chains, Arg 45 and Arg 68. The positive field generated by the antibody residue Arg L93 gives rise to a dipole, close to the antibody surface, perhaps helping to preorient the antigen at its approach to the binding site.

Plate 38

Plate 38 (C) Comparison of anti-digoxin and anti-lysozyme binding sites. In these 'elevation plots', points of the molecular surfaces, generated by the program GRASP, have been color-coded according to its distance normal to a three-dimensional envelope of the molecule. The envelope was defined, and constructed, as a smooth, curved plane connecting the 'highest' peaks of the molecular surface. The deepest protrusions on the surface of the molecule are shown in blue, the most elevated points of the surface are shown in red. The binding site of the 26-10 antibody directed against the hapten digoxin is a deep, narrow well (high 'global' curvature); the binding sites of the anti-lysozyme antibodies D1.3 (crystallographic coordinates by Bhat TN *et al.*, (1990) *Nature* **347**: 483-486, HyHEL-5 and HyHEL-10 (coordinates by Padlan EA *et al.*, (1989) *Proceedings of the National Academy of Science of the USA* **86**: 5938-5942) are all larger and more shallow (low 'global' curvature). The D1.3 binding site contains a smaller, deep 'local' hole in its surface (complementary to the lysozyme residue Gin 121), the HyHEL-5 binding site contains a similar but shallower hole (complementary to Arg '68,). The HyHEL-10 elevation plot shows virtually no local depressions. (Kindly provided by J Novotny and M Davis, Bristol-Myers Squibb Research Institute, USA with permission.)

Plate 39

Plate 39 Antibody cross-reaction. DB3 antibody binding site in complex with four different cross-reacting steroid haptens. The elevation plots shown here were prepared as described in the legend to Plate 6 (C). Surface color-coding is from red (most elevated) to blue (the deepest). Crystallographic coordinates by Arevalo JH *et al* (1994). *Journal of Molecular Biology* **241**: 663-680. Upper left, DB3 with progesterone; upper right DB3 with 3-aetiocholanolone (5- β -androsterane-3, 17-dione); lower left, DB3 with 5- α -pregnane-3- β -hemisuccinate; lower right, DB3 with 3-progesterone-11- α -olsuccinate. Haptens are shown in stick representations; carbons are color-coded white, oxygens red. It can be seen that the overall shape of the binding site does not change on engaging the cross-reacting ligands; rather, the steroids orient themselves differently with respect to the binding site cavity. At the periphery of the binding site, however, changes to the shape of the surface can be seen, due to surface side-chain rearrangements. (Kindly provided by J Novotny and M Davis, Bristol-Myers Squibb Research Institute, USA with permission.)

Plate 40

Plate 40 Epitopes on neuraminidase. The two energetic epitopes (NC41 and NC10) on the surface of the influenza N9 neuraminidase. The calculated 'energetic' epitopes (Tulip WR *et al.*, (1994) *Biochemistry* **343**: 7986-7994) were color-coded, antibody-antigen from green (residues with free energy contributions stabilizing the complex), through white ('neutral' residues), to red (residues whose contributions to the free energy of binding destabilize the complex). Although the two epitopes overlap by about 80%, their binding free energy attribution is strikingly different. (Kindly provided by J Novotny and M Davis, Bristol-Myers Squibb Research Institute, USA with permission.)

Plate 41

Plate 41 Superantigen. Molscript model of *Staphylococcus enterotoxin A* (SEA) interacting with two MHC class II molecules. SEA is colored red, MHC class II and bound peptide blue and purple, respectively. On the left-hand side MHC class II β -chain contacts the SEA coordinated zinc ion (yellow) through a histidine residue on the MHC class II β chain (His81, illustrated as ball-and-chain). The right-hand side shows the interaction between MHC class II α chain and SEA. This point of interaction is centered around a phenylalanine residue in SEA (Phe47, illustrated as ball-and-chain) and a lysine residue in MHC class II α chain (Lys39, illustrated as ball-and-chain). A

ABO BLOOD GROUP SYSTEM

Anatole Lubenko and Marcela Contreras, North London Blood Transfusion Centre, Colindale Avenue, London, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The ABO blood group system was discovered by Landsteiner in 1901. By mixing separated sera with suspensions of red cells obtained from the blood of different individuals, four patterns of agglutination could be obtained. The frequency of the four ABO groups varies in different populations: Amerindians are almost exclusively group O while Asians have a higher incidence of group B. In the UK the proportions of the four main blood groups are as follows: O (46.5%), A (42%), B (8.5%) and AB (3%). Agglutination of red cells arises because one individual's serum contains naturally occurring antibodies against ABO antigens that are missing from that individual's own red cells, but which are present on the cells of another; e.g. group A individuals have anti-B that agglutinates group B cells (see Table 1). Testing of red cells with selected potent anti-A, -B and -A,B reagents, while simultaneously testing the sera of the same subjects with reagent red cells (group A₁, A₂, B and O), provides the basis for ABO grouping (see Table 1).

The major subgroups of A are A₁ and A₂; the difference between them is partly quantitative and

partly qualitative. These subgroups can be distinguished using specific anti-A₁ reagents, and are only significant clinically if the serum of an A₂ individual reacts at 37°C, which may hence cause destruction of transfused group A₁ red cells. Quantitative variants of A (A_{int}, A_x, A_{end}, A₃, A_m, A_y, A_{cl}, etc.) and B (B₃, B_x, B_m, B_i, B_{ii}, B_{cl}, etc.) are also known, which are characterized by the absence of the appropriate ABO antibodies from their plasma; e.g. the cells of A_x individuals fail to react with anti-A from B subjects although they react with strong anti-A in group O subjects; such individuals do not have anti-A. A and B variants are rare and usually of little clinical significance.

Genetics

The genes controlling the expression of A or B antigens are autosomal codominant alleles (A and B respectively) that map to the 9q34 region of chromosome 9. Because the A and B antigens are sugars, the genes coding for ABO are glycosyltransferases. Group O individuals possess alleles at the ABO locus

Table 1 ABO grouping

ABO group	Agglutination of test cells with reagent				Agglutination by subject's plasma of control cells of group			
	Anti-A	Anti-A ₁ ^a	Anti-B	Anti-A,B	A ₁	A ₂	B	O
A ₁	+	+	0	+	0	0	+	0
A ₂	+	0	0	+	+/ ^{0b}	0	+	0
B	0	0	+	+	+	+	0	0
A ₁ B	+	+	+	+	0	0	0	0
A ₂ B	+	0	+	+	+/ ^{0b}	0	0	0
O	0	0	0	0	+	+	+	0

^aAnti-A₁ reagents can be: a lectin prepared from *Dolichos biflorus* seeds; sera of group B subjects absorbed with group A₂ red cells; or mouse monoclonal antibodies.

^bThe plasma of 1–8% of group A₂ and 22–35% of group A₂B individuals have weak naturally occurring anti-A₁.

on both homologous chromosomes that code for functionally inert proteins (see below), while A and B code for an *N*-acetylgalactosaminyl- and galactosyltransferase respectively. The appropriate alleles that encode the A¹, A² and B-transferases have been cloned and sequenced. The A and B genes code for 41 kDa proteins composed of 353 amino acids, which contain a 21 amino acid long leader peptide that is cleaved off to form the mature transferase. The two genes differ at seven nucleotide positions, which generate only four amino acid differences, found at positions 176, 235, 266 and 268 of the A- or B-transferase polypeptide. These correspond to Arg, Gly, Leu and Gly in the A-transferase, and to Gly, Ser, Met and Ala, respectively, in the B-transferase. The most critical differences are at positions 266 and 268 but the four are collectively responsible for the immunochemical differences between A and B and their associated transferases; substitution of one or more of these four key amino acids can critically affect ABO expression (see O² below).

Three types of O alleles have been described to date; the commonest has a nucleotide sequence similar to that of the A allele, but with a single base deletion that generates a change in reading frame (hence scrambling the amino acid sequence) at amino acid position 87. This deletion also produces a new in-frame stop codon that generates a truncated O allele polypeptide that is only 116 amino acids long, and which is enzymically inactive. An analogous O allele, with an incidence one-quarter of that of the former and representing an equivalent single base deletion in a B gene, has also been reported. The third type of O (sometimes called O²) arises from Arg→Gly and Gly→Arg substitutions at amino acids 176 and 268, respectively, of an A allele which abolishes the enzymatic activity of the resulting protein, thereby emphasizing the metabolic importance of these amino acids at the transferase active site.

The differences between the A¹ and A² alleles arise from a Pro→Leu mutation at amino acid position 156 coupled to a single base deletion near the C-terminus of an equivalent A¹-allele. This in turn results in a frame shift so that the original stop codon is no longer recognized, and a new stop codon is generated downstream, giving rise to a polypeptide for the A² enzyme that is 21 amino acids longer than the A¹ enzyme. The extra sequence thus generated, together with the Pro-Leu substitution in the A²-transferase, should account for the differences in kinetics and specificity between the two enzymes (see below). In addition to A¹ and A², the alleles encoding several examples of various other ABO subgroups have also been cloned: A₃, A_x, B₃, B(A) and *cis*-AB. All have so far proven to be heterogeneous at the

nucleotide level despite having been considered to characterize a single phenotypic subtype.

The A- and B-transferases synthesize A and B carbohydrate antigens by transfer of *N*-acetylgalactosamine (GalNAc) or galactose (Gal) moieties from UDP-GalNAc or UDP-Gal respectively to the C-3 carbon atom of a fucosylated terminal galactose residue present in a variety of oligosaccharide precursors with blood group H activity (see Figure 1). These precursors are the sugar component of glycolipids and glycoproteins. The transferases of the A₁ and A₂ alleles are known to have different pH optima, isoelectric points, thermal stabilities and metal ion cofactor requirements, which result in differences in their substrate transfer kinetics.

It is rarely possible to deduce a genotype from an ABO phenotype unless the groups of the family are available. For example, a group B individual could be B/B or B/O; an A₁ subject could be A¹/A¹, A¹/A² or even A¹/O. In contrast, group AB and group O individuals are A/B and O/O respectively, unless they are of the extremely rare *cis*-AB (with A and B antigens both derived from a rare allele at a single locus) or O 'Bombay' (see below) phenotypes.

Knowledge of the nucleotide sequences that distinguish the ABO alleles has enabled primers to be designed that can be used to determine ABO genotypes through the application of PCR. These include sequence specific primers that uniquely amplify A, B or O, as well as generic primers that amplify all ABO alleles; the products of the latter are distinguished by their sensitivity to restriction endonucleases that recognize the DNA sequences of specific ABO alleles.

ABO epitopes

ABO antigens are synthesized by glycosylation of oligosaccharides with H antigen activity. The H antigen is synthesized by a fucosyltransferase that is the product of the H gene on the long arm of chromosome 19. Carbohydrate chains carrying the A, B, and H antigens are present on 1) the short-chain oligosaccharides of simple glycolipids in plasma; 2) the heavily branched polysaccharides that form the polyglycosyl moieties of either soluble glycoproteins present in secretions or of polyglycosyl ceramides in the red cell membrane, and 3) the short O-linked and highly branched N-linked polysaccharides of integral membrane proteins. The immunodominant sugars of the A and B antigens are at the terminal (non-reducing end) of the various polysaccharide chains expressing A or B, and are invariably attached by an α1-3 linkage to a fucosylated galactose residue with H antigen activity (see Figure 1) such that the simplest A epitope is a trisaccharide with the structure:

Figure 1 Biosynthetic pathways for the synthesis of A, B and H structures on type 1 precursor chains.

where R represents the rest of the polysaccharide chain. The B epitopes have Gal instead of GalNAc as the immunodominant sugar. The presence of the fucosyl residue, i.e. the H antigen, is essential for A and B expression: its absence, as in the rare 'Bombay' phenotype, leads to an inability of the A- and B-transferases to add their respective sugars to the Gal part of Gal—R, and hence A and B antigens are not expressed, even though the relevant transferases can be detected in cells and plasma and are functionally active in *in vitro* assays using fucosylated substrates from normal subjects as acceptors. Such 'Bombay' individuals lack an H gene, being homozygous for the silent allele h.

The terminal trisaccharides can be attached to R in at least six different ways: e.g. by either a 1–3 or 1–4 linkage to β GlcNAc (type 1 and type 2 A or B structures respectively), by a 1–3 link to α GalNAc (type 3), β GalNAc (type 4) or β Gal (type 5) or even a 1–4 link to β Glc (type 6). Of these, types 1 and 2 are the more abundant in the red cell membrane and the most important in red cell serology: integral red cell membrane proteins and glycolipids have almost exclusively type 2 linked sugars. Red cells may also contain glycolipids, passively adsorbed from plasma, that have exclusively type 1 chains. Secretions have a mixture of type 1 and type 2 epitopes. The existence of these various epitopes probably explains the heterogeneity in reactivity of different ABO antibodies with group A or B variants; seven reaction patterns for monoclonal anti-A and anti-B have been described.

In secretory tissues and other epithelia, ABH antigen expression is modulated by the genes of the 'secretor' (Se) locus which is not linked to the ABO locus; nonsecretor (se/se) individuals fail to produce type 1 and type 2 H in their secretions whereas red cell (type 2) H expression is unaffected.

Expression of ABO on red cells may be deliberately modified by treatment with glycosidases: an α -galactosidase extractable from green coffee beans can remove galactose from group B red cells and hence enzymically convert them to group O. Such 'ECO' (enzymically converted group O) red cells may survive normally when transfused to group O subjects. However, the clinical potential of such techniques is limited.

Biosynthesis and ontogeny

The A- and B-transferases and their respective antigens in adults are most abundant in intestinal and gastric mucosa, lungs and salivary glands. Significant levels are found in kidneys, bladder, urothelial cells, bone marrow and hematopoietic cells. The enzymes exist in the cytoplasm and bound to the membranes of the cells of the above tissues and in the membranes of red cells and platelets. The transferases are in free solution in the transtubular network and their relevant secretions, e.g. mucin droplets, plasma, ovarian cyst fluid, milk, saliva. Molecules glycosylated by the transferases include membrane enzymes, membrane structural proteins and receptors, as well as secreted proteins, e.g. IgA. The ABO transferases, but not others, can be lost in various cancers, e.g. carcinoma of the bladder and of the colon. Both N-linked and O-linked oligosaccharide moieties of glycoproteins with A or B activity are synthesized in the Golgi.

During ontogeny, ABH (and Lewis) activity is at its highest in the early embryo from the 5th week postfertilization; ABH antigens are found in large amounts on endothelial cells and most epithelial primordia, and in practically all early organs e.g. blood islands of the yolk sac, erythropoietic foci of the liver; digestive tube epithelia, pharyngeal pouches, the thymus, the pituitary, thyroid glands, trachea and bronchi, hepatic and pancreatic diverticula, the cloaca, urachos and allantois, mesonephros and the ducts of the metanephros. The CNS, liver, adrenal glands and secretory tubules show no ABH activity at this stage.

From the end of the 12–14th week of gestation, there is regression of ABH expression from epithelial cell walls, thyroid pituitary, and other glands and organs, to the adult vestigial pattern described above. The biological significance of this regression is unknown. The number of A and B sites on the red

cell is increased approximately fourfold in adults as compared with newborn infants, such that there are $0.25\text{--}0.37 \times 10^6$ A sites per red cell in the newborn and $0.81\text{--}1.2 \times 10^6$ in the adult, as compared with $0.2\text{--}0.32 \times 10^6$ B sites per red cell in the newborn and 0.75×10^6 for adults.

A- and B-like antigens have been detected in a variety of microorganisms and animal tissues. During phylogeny, ABH antigens are confined to the endodermal tissues of amphibia and reptiles, and are present on the epidermis of all mammals studied to date. While ABH is found on baboon vascular endothelium, only humans and the great apes have red cells expressing ABH. ABO are 'histocompatibility' antigens; it is simply the peculiarity of their original description that has led to ABH antigens being thought of as 'blood groups'.

ABO antibodies

The clinical importance of the ABO blood group system derives from the universality of its antibodies and their *in vivo* potency. The 'naturally occurring' antibodies of the majority of group A or B individuals are mainly IgM and produced in response to environmental ABO antigens, e.g. from microbes in the gut and respiratory tract. Such IgM antibodies, although displaying optimal activity in the cold, are reactive at 37°C and can activate the complement cascade up to the C9 stage, leading to the immediate intravascular lysis of transfused incompatible red cells *in vivo*. In the UK, roughly one in every three randomly selected, ungrouped blood donations would be incompatible with a given recipient; such incompatible transfusions can lead to renal failure, disseminated intravascular coagulation and even death. The majority of the signs and symptoms of severe ABO hemolytic transfusion reactions can be attributed to the generation of C3a and C5a fragments as a result of complement fixation, with the consequent release of vasoactive amines from mast cells and of cytokines such as interleukin-1 (IL-1), IL-6, IL-8 and tumor necrosis factor α (TNF α) from mononuclear cells.

Most, if not all, group O adults, and a small proportion of group A and B subjects, have naturally occurring, usually weak, IgG in addition to stronger IgM ABO antibodies. The IgG component can cross the placenta and bind to fetal red cells; however, lysis of fetal red cells is generally minimal and hemolytic disease of the newborn (HDN) caused by ABO antibodies is usually mild or inapparent in Western Europe and North America. The occurrence of HDN due to ABO antibodies cannot be predicted, but it only affects the offspring of group O mothers. The

lack of severity of most cases of ABO HDN is thought to be due to: 1) IgG ABO antibodies being predominantly IgG2, which is incapable of initiating complement-mediated hemolysis or destruction of antibody-coated red cells by the mononuclear phagocytic system (many sera have IgG1 ABO antibodies as well as an IgG2 component; a few sera have trace amounts of IgG3 and IgG4 antibodies); 2) substantial amounts of maternal IgG ABO antibodies binding to ABO sites on tissues other than red cells in the fetus; 3) soluble ABH antigens in plasma and body fluids of the fetus which neutralize IgG anti-A and anti-B and inhibit their binding; 4) the ABO epitopes of fetal red cells being present on unbranched oligosaccharides, which are thought to be unable to support the divalent IgG binding needed for complement activation by IgG1 or IgG3 antibodies; 5) fetal complement levels being too low to support efficient lysis of cord (or even adult) target red cells. However, in some parts of the world, ABO HDN is often more severe and this is attributed to environmental factors such as the stimulation of ABO antibodies by microbes and parasites.

Some individuals possess plasma IgA ABO antibodies irrespective of immunization; ABO antibodies of colostrum are often wholly IgA, although sometimes IgM antibodies can also be found.

Cord blood usually does not contain ABO antibodies although maternally derived IgG anti-A or -B can sometimes be detected. Newborn infants do not produce ABO antibodies until the 3rd–6th month of age (median titer = 4), reaching a maximal titer (approx. = 128) between the ages of 5 and 10 years. Anti-A seems to attain higher titers more rapidly than anti-B. Adult titers of anti-A range from 32 to 2048 (median = 256) and anti-B from 8 to 512 (median = 64). The vast majority of healthy adults

have readily detected ABO antibodies. Weakening of ABO antibodies can occur naturally in individuals aged over 50; a third of patients over 65 have ABO antibody titers of 4 or less. Occasional subjects may lack the appropriate ABO agglutinins, especially if hypogammaglobulinemic, or if their plasma IgM levels are low. Antibodies can be lost by exhaustive plasma exchange (used therapeutically in ABO incompatible bone marrow and organ transplantation) or by immunosuppression caused by therapy or by disease. IgM anti-A or -B are completely absent in individuals with the very rare Wiskott–Aldrich syndrome.

ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS)

Anthony J Pinching, Department of Immunology, St Bartholomew's and the Royal London School of Medicine and Dentistry, Queen Mary and Westfield College, University of London, London, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

In the early 1980s, reports appeared of a new immunodeficiency disease, which was later called the acquired immune deficiency syndrome or AIDS. Over the following decade and a half, the scale of AIDS has risen from a mere handful of cases in the USA to hundreds of thousands of cases affecting most countries worldwide. The human immunodeficiency viruses (HIV-1 and HIV-2), the causative retroviruses of AIDS, have already spread to 15–20 million individuals in less than three decades, and continue to spread rapidly in many communities, especially in the developing world. This epidemic of profound immunodeficiency, predominantly affecting cell-mediated immunity, has had a devastating and pervasive impact on many individuals and societies and has presented many challenges to immunology and to other clinical and scientific disciplines. Although an inadequate counterweight to its tragic personal and social impact, AIDS has served to focus and increase our knowledge of the immune system in health and disease as well as our understanding of individuals and of human society.

Epidemiology

Although the first cases of AIDS were seen in homosexual men in the USA, it soon became apparent that the epidemic of HIV and AIDS was occurring more widely in North America, Europe and Australasia, not only among homosexual men but also among intravenous drug users, recipients of blood and blood products, notably hemophiliacs, and to a lesser extent among heterosexual men and women, and among children of HIV-infected women. It also gradually emerged that a substantial epidemic was affecting several regions in the developing world, such as sub-Saharan Africa and the Caribbean, with a somewhat different pattern of infection, predominantly affecting heterosexual men and women and their children, as well as recipients of blood transfusions. South America showed a mixture of the two patterns, while other regions such as the Middle East and Asia initially showed a lower incidence of a type more similar to that seen in Africa. In the late 1980s, there was a rapid expansion of the epidemics in India and South-East Asia, predominantly through heterosexual spread and among injecting drug users.

These epidemics are almost entirely due to HIV-1, although there is regional variation in serotypes. Type B virus is found mainly in the USA and Europe, while other serotypes are seen in Africa and Asia; it has recently been suggested that type E, found in parts of Thailand, may have a greater capacity for heterosexual transmission. HIV-2, a related virus, has been seen in West Africa and remains largely restricted to that region. It appears to be less readily transmissible (though by the same routes) and is also less pathogenic, but causes the same spectrum of disease as HIV-1.

Such overall patterns of spread, together with detailed case and cluster studies, indicated that HIV was spread by three routes: sexual transmission, transmission by blood and from an infected mother to the fetus. Sexual transmission could occur through penetrative intercourse between homosexual men or between men and women. Regional differences in the type of sexual spread mainly reflect differences in prevalent sexual behavioural patterns and frequency of sexual partner change. Intercurrent sexually transmitted infections, especially those associated with genital ulceration, in either partner increase the risk of transmission but are clearly not essential. Blood-borne transmission occurred through transfusion of blood or blood products, but also, on a larger scale, between intravenous drug users who shared needles and syringes and other equipment; there is a small but definite risk of infection through inoculation injury. Vertical transmission occurs in part transplacentally, in part during delivery and in part through breastfeeding, although the proportions remain uncertain. Casual transmission has not been documented.

There has been considerable interest in the possibility that individuals exposed to HIV may develop protective immunity that prevents or clears initial infection or have features that prevent or reduce the risk of subsequent infection. For example, cohorts of female prostitutes in Africa and of homosexual men include individuals who appear to have been multiply exposed but remain uninfected. These show some HLA association and evidence of HIV-specific cytotoxic immune responses. The mechanism remains obscure. Recent observations on second receptors for

HIV, which are variably expressed among some populations, raise the possibility that lack of such receptors could be protective. Some infants appear to show evidence of transient infection as evidenced by polymerase chain reaction (PCR) or viral culture in the weeks after delivery but do not seroconvert or show any other signs of infection later. It has been proposed that they have cleared the infection, although the possibility of prolonged circulation of latently infected maternal cells has not been excluded.

Spectrum of HIV infection

A person infected by HIV will, within 3 weeks to 3 months, develop a detectable antibody response and will remain HIV antibody positive thereafter. Given that HIV establishes persistent infection, antibody positivity can be taken as evidence of current infection and has been widely used clinically and epidemiologically as a marker.

At the time of seroconversion, a significant minority of patients develop an acute transient glandular fever-like illness, with fever, malaise, rash, sore throat, lymphadenopathy, arthralgia and headaches (HIV seroconversion illness). In a few cases there is frank encephalopathy or aseptic meningitis. It is also now recognized that some patients develop acute, transient cellular immunodeficiency, manifested, for example, by oral and esophageal candidiasis. The symptoms and signs of acute HIV infection typically resolve after a few weeks. Patients with a severe and prolonged acute illness appear to progress to AIDS more rapidly, and those who develop any symptomatic seroconversion are more likely to progress than those who do not. After the resolution of the acute illness, patients will pass into a phase of chronic symptomless HIV infection.

Chronic symptomless HIV infection may take one of two forms – patients without any abnormal physical signs and those with persistent generalized lymphadenopathy. The lymph nodes are in most instances moderately enlarged in cervical, axillary and inguinal regions (although inguinal nodes may be enlarged to a similar degree in people without HIV infection) and some other peripheral sites, such as the epitrochlear nodes. They are sometimes slightly tender and may fluctuate in size with intercurrent illness, but are otherwise unremarkable. Patients may remain symptomless, with or without enlarged lymph nodes, for many years but over time a substantial proportion go on to develop disease. The risk for developing symptomatic disease is similar for patients with and without lymphadenopathy.

A few patients with otherwise symptomless

chronic infection and without immunodeficiency develop thrombocytopenic purpura. The pathogenesis of this is somewhat unclear, with evidence for platelet-specific antibodies and for immune complexes in different studies. The disorder is rarely associated with severe bleeding and seems to remit spontaneously after a few years in most cases. It does not presage progression.

With increasing years of infection, an increasing proportion of patients with chronic HIV infection will progress to develop evidence of immunodeficiency and other disease. This may initially be seen as constitutional illness (malaise, weight loss, diarrhea) or evidence of moderately severe immunodeficiency (oral candidiasis, oral hairy leukoplakia, multidermatomal shingles, salmonellosis). Patients may first develop such symptoms and later progress to AIDS, while others develop AIDS without any intervening symptomatic stage.

AIDS itself comprises two main categories: patients with major opportunist infections of cell-mediated type (e.g. *Pneumocystis carinii* pneumonia, cryptococcal meningitis, disseminated mycobacterial infection, cytomegalovirus retinitis), and those with opportunist tumors, Kaposi's sarcoma and B cell lymphoma. These will be considered in more detail below. It is worth noting that patients with Kaposi's sarcoma alone and some patients with lymphoma have less severe immunodeficiency than those with major opportunist infections.

In addition to the problems with cell-mediated opportunists, some patients, especially children, show significantly increased susceptibility to infections with capsulated bacteria of a type more typically associated with humoral immunodeficiency. This results from the dysglobulinemia seen in HIV infection, in which there is immunoglobulin G2 (IgG2) subclass deficiency and impairment of specific antibody development against antigens not previously encountered. These infections can occur with increased incidence in people with otherwise symptomless infection.

As well as its immunopathogenic effects, HIV can also cause chronic progressive disease of the nervous system, including HIV encephalopathy (or AIDS dementia complex), vacuolar myelopathy, peripheral and autonomic neuropathy, and occasionally an inflammatory myopathy. The central nervous system disorders typically occur after the onset of immunodeficiency disease, but go on to affect a high proportion to varying degrees.

A variety of other clinical disorders are seen, including: lymphocytic interstitial pneumonitis and an associated chronic lymphocytic parotitis, which are commonly seen in children but rarely in adults:

the appearance or increased severity of psoriasis and Reiter's syndrome and other seronegative arthropathies; HIV enteropathy with partial villous atrophy; and recrudescence of atopic disease in predisposed subjects.

Clinical features of AIDS

The profound and progressive immunodeficiency seen in AIDS is broadly characterized by infections with facultative intracellular and related pathogens and herpesviruses, and by opportunist tumors. While some of these pathogens only cause disease in immunodeficient subjects, others show altered and enhanced pathogenicity, causing different clinical disorders or more disseminated disease. The profile of these infections shows regional variation determined by locally prevalent pathogens and risk behaviour, which also affect the likelihood of infection by the relevant organisms, many of which are latent in the immunocompetent host.

Common and early infections in AIDS include *Pneumocystis carinii* pneumonia, disseminated tuberculosis, esophageal candidiasis, cryptococcal meningitis and ulcerative mucocutaneous herpes simplex infection. Other common infections seen, typically later in the course of the progressive decline in cell-mediated immunity, include cerebral toxoplasmosis, cytomegalovirus disease (presenting as retinitis, colitis, esophagitis and adenitis and, less often, pneumonitis, encephalitis and radiculitis), disseminated *Mycobacterium avium intracellulare* infection, histoplasmosis, gastrointestinal cryptosporidiosis, progressive multifocal leukoencephalopathy, visceral leishmaniasis, disseminated penicilliosis, nocardiosis and disseminated strongyloidiasis. Some of these organisms present predominantly in one organ system – lungs, gut, central nervous system, lymph nodes – but may also show varying degrees of dissemination.

Kaposi's sarcoma, which is most common among homosexual men and among heterosexually acquired cases of HIV in the developing world, is thought to result from infection with a newly recognized human herpesvirus, HHV-8. It often presents as cutaneous disease, later progressing in some patients to affect lymph nodes, lungs and gastrointestinal tract. Severe visceral disease more commonly presents early in patients in Africa. B cell lymphoma, of a variety of histological types, may present as isolated cerebral lymphoma or as systemic disease, with frequent extranodal involvement. Hodgkin's lymphoma, seminoma, squamous carcinoma of the anorectal region, cervical carcinoma and acute myeloid leukemia have also been observed somewhat more

frequently in HIV-infected subjects, although the association is less clear.

Natural history of HIV infection

The risk of development of disease in HIV-infected subjects has been assessed in large cohort studies. These have shown that in time the majority will develop AIDS (50% in 10 years; 65% in 14), with others progressing to less severe symptomatic HIV disease. It is now recognized that a small proportion of patients remain well and without evidence of immunodeficiency for 10 or more years. It is not clear whether they represent a discrete group or simply those with much slower progression rates. They are the subject of many studies attempting to define whether there are immune or other protective mechanisms.

Several factors affecting the likelihood of progression in HIV-infected subjects have been identified. Increased risk of disease and of immunological decline has been shown in patients with the HLA-A1, -B8, -DR3 haplotype in cohorts of hemophiliacs and homosexual men and HLA-B35 may also increase the risk of progression. In some ethnic groups HLA-DR5 is associated with increased risk of Kaposi's sarcoma. Patients with HLA-B27 appear to have a lower risk of progression.

Intercurrent infections may also affect progression: evidence of such an effect has been shown for sexually transmitted infections among homosexual men and for cytomegalovirus infection among hemophiliacs. It is plausible that other infections may have a similar effect, including systemic bacterial infections in injecting drug users using unsterile equipment, and possibly some of the infections that result from immunodeficiency, such as tuberculosis, listeriosis and pneumocystosis.

Age may also have some effect. This is most clearly seen in children infected in the neonatal period who show a much higher proportion of rapid progressions than adults. This is unlikely to reflect immunological immaturity and may result from immunological activation during the acquisition of an immunological repertoire. Children over 4 years of age show similar progression rates to adults. Adults over 50 years of age may also have slightly increased risk of progression.

The effect of pregnancy is controversial. Early studies that were carried out on women who had already given birth to a child with AIDS showed that subsequent pregnancies were associated with increased risk of progressive disease in the mother. More recent studies on women having their first HIV-positive pregnancy indicate no increased risk. It

is possible to reconcile these findings by concluding that having more than one HIV-positive pregnancy increases the risk to the mother.

Although formal epidemiological data are lacking, it is plausible that malnutrition, which itself induces cell-mediated immunodeficiency, may enhance the risk of progression to HIV disease. A higher rate of progression has been reported in a prospectively studied cohort in Uganda; several factors could have contributed to this, including different viral strains, different human genotypes, intercurrent parasitic and other infections and nutritional state. The use of immunosuppressive drugs such as prolonged high doses of corticosteroids may enhance risk.

The overall picture is one where increased risk of progression is associated with events that may activate the immune system, and thus active CD4 lymphocytes and macrophages which are latently infected with HIV, hence increasing virus replication, cell-to-cell spread and progressive immunological decline, as well as with events that suppress cell-mediated immune responses, thus compounding the factors leading to immunological deterioration.

Some strains of virus, whether the initially infecting virus or one that emerges through mutation within the infected host, may have greater pathogenic potential. One transfusion-associated cluster of HIV infections has been reported in which long-term nonprogression was a feature and where the HIV strain had a defective *nef* gene; this does not appear to be a generalizable feature but indicates the role of viral genotype, as do the lower rates of progression with HIV-2.

The role of protective immunity, whether humoral or cell mediated, is far from clear. Neither neutralizing antibody titer nor HIV-specific cytotoxicity, whether of antibody-dependent type or major histocompatibility complex (MHC)-restricted type, have any consistent relationship with progression. These responses are present throughout the spectrum of HIV infection and disease. It remains to be established whether or not innate resistance or susceptibility to HIV infection or disease play any part, or whether genetic factors serve rather to influence the ease with which, for example, immunological activation by intercurrent events is achieved, as is implied by the association with the HLA-A1, -B8, -DR3 phenotype. The study of long-term nonprogressors has attempted to elicit evidence of special features associated with nonprogression but has not yet shown any unique or general characteristic of host or virus. One problem with such studies is that of finding an appropriate comparator group, as their rapidly progressing peers may already have died and

current rapid progressors may have different initial host and viral characteristics.

Predictive markers for progression

Another objective of cohort analysis has been the identification of markers that can predict risk of future progression in HIV-infected subjects. The numbers of CD4 cells in blood have been widely used in this way, not least because they can reflect a significant component of the pathogenesis of disease. In grouped data over long-term follow-up, falling CD4 counts are strongly associated with progression. However, there is considerable variability in individual trends and, as many other factors can affect CD4 count, CD4 counts must be used with caution in individual patients. Serum markers of immunological activation such as β_2 -microglobulin, neopterin and interleukin 2 (IL-2) receptor are also associated with an increased risk of progression, as are raised IgA levels. The CD8 count may rise during the early years of HIV infection and then fall in the 2 years before progression, but the predictive value is unclear. CD8 derived cytokines may inhibit virus spread.

Virological markers are also of value. In early studies, HIV p24 antigenemia was strongly associated with progression in patients in temperate climates, although a significant proportion of AIDS patients do not develop antigenemia. Prior to the appearance of HIV p24 antigen, antibody levels against p24 fall, perhaps reflecting the complexing of p24 antigen and antibody following increased virus replication. Reduced levels of antibodies to p17 and to reverse transcriptase may show similar trends. These changes are not seen in patients in tropical environments, perhaps due to increased polyclonal B cell activation due to parasitic and other infections. It is evident that p24 antigen is an imperfect and crude index of virus replication.

Recently, it has become possible to measure viral load by quantitative PCR. Studies on a large prospective cohort of HIV-infected individuals have shown that viral load measures on initial samples provide a powerful predictive marker for subsequent progression. Such tests appear to be more discriminatory than CD4 count alone. Such findings are likely to provide a valuable means of assessing prognosis and suitability for antiretroviral therapy. They may help to identify those subjects with a high CD4 count who do poorly and those with a low CD4 counts who do well. Although the use of the two markers in conjunction has yet to be analyzed, this is likely to be a particularly useful combination for assessing future progression. Longitudinal analysis of both markers

may add further value. Earlier data showed that combining CD4 counts with serum neopterin, IgA, IL-2 receptor and p24 antigen could provide a better prediction of outcome than CD4 alone, although these are likely to be superseded by viral load measures, which probably correlate with activation markers.

Immunopathogenesis

HIV is a retrovirus, having an RNA gene that encodes for reverse transcriptase, which allows a DNA copy of the virus to be made. This DNA copy is then spliced into the gene of the infected cell, through the action of virally encoded endonuclease, leading to persistent and typically productive infection.

A major HIV gene product is the outer envelope glycoprotein gp120, which is expressed on the surface of the virus and of infected cells, and contains a region which binds with high affinity to the CD4 molecule on host cells. CD4 thus acts as the main virus receptor, enabling HIV gp120 to target cells of the immune system for infection and subsequent damage. Second receptors (CXCR4 and CCR5) for HIV on CD4 T lymphocytes and on antigen-presenting cells are a family of transmembrane proteins which are physiological receptors for chemokines. They appear to be critical to fusion events and cellular infectivity, and may also explain data showing that combinations of chemokines (RANTES, MIP-1 α and MIP-1 β) can inhibit cell-to-cell infection *in vitro*.

After the attachment of gp120 to CD4 and the second receptor on lymphocytes or macrophages, the virus membrane fuses with the membrane of the CD4-bearing cell, internalizing the virus genome and leading to cellular infection. This occurs both in initial infection and in the gradual process of cell-to-cell spread within the body that leads ultimately to disease. Infection of CD4 lymphocytes is central to the immunopathogenetic effects of HIV. Macrophages and related cells can also be infected by routes other than CD4 binding, e.g. Fc or C3b receptor binding. Such cells serve as an important reservoir of HIV infection and are implicated in the neuropathogenesis of HIV encephalopathy. Recent data have emphasized that most cell-to-cell infection occurs in lymphoid tissue, where extensive viral replication has been documented. As disease progresses, this results in significant structural damage to these key microenvironments.

The viral replication cycle proceeds at a rapid rate in infected patients, with durations of as little as 2.6 days, giving some 140 generations each year. This, combined with the error-prone transcription of retroviral genes, gives the opportunity for enormous

diversity of viruses within any individual. It is against this background that pathogenetically diverse strains, such as syncytium-inducing strains, and drug-resistant strains may emerge. In turn these affect the rate of immunological decline and responsiveness to therapy.

The most striking and most consistent effects of HIV in progressive disease are a reduction both in the number and in the function of CD4 lymphocytes. Infection of CD4 lymphocytes by HIV leads to their premature death or rapid elimination, so that few viable circulating CD4 cells show evidence of infection at any time, yet their numbers are progressively depleted. This may be due to virus cytopathic effects or to host-mediated cytotoxicity, or both. Virus-induced damage includes cell lysis and, more importantly, apoptosis and the formation of syncytia by fusion of infected as well as uninfected CD4 lymphocytes.

In addition to the progressive attrition of CD4 lymphocytes, various defects in the function of the CD4 cells that remain have been shown, even though most of them are uninfected at the time. These include failure of T cell responses to antigen, to T cell mitogens (phytohemagglutinin, concanavalin A) and to T cell-dependent B cell mitogen (pokeweed), whether measured by proliferation or cytokine/antibody production. Impaired cytokine release is seen for IL-2 and macrophage-activating cytokines such as interferon γ , as well as cytokines involved in regulating B cell responses. It seems that the failure of these mechanisms is largely responsible for the defects in killing of facultative intracellular pathogens, failure to control virally-induced tumors and herpesvirus infection and for some of the B cell defects seen in patients.

One common means whereby these effects on CD4 cell function could be mediated by HIV has been shown. HIV infection of lymphocytes *in vitro* or exposure of uninfected lymphocytes to gp120 causes activation of the inositol polyphosphate (InsP) signal transduction pathway; this causes a rise in resting levels of InsP₃ and InsP₄, and hence of intracellular calcium. This leads to a state of chronic cellular activation, rendering the cells less responsive to new signals. Similar changes are seen in lymphocytes taken from patients. These effects may be mediated by binding to CD4 and subsequent alterations in the intracellular signaling pathways involving tyrosine phosphorylation, starting with p56^{lck}. Similar changes in activation are seen in macrophages and it is possible that similar effects underlie the effect of HIV proteins on B cell function.

Depletion of CD4 lymphocytes and their functional impairment has knock-on effects on many

other cells, in addition to any direct effects that HIV has on them. Patients' macrophages show impaired microbicidal activity for intracellular pathogens in the presence of cytokines produced by autologous lymphocytes, although they retain responsiveness to exogenous interferon γ . Other macrophage functions, including antigen-presenting function and receptor expression, show changes that may result from loss of CD4 lymphocyte signals or from HIV infection. Dendritic cells, which may be infected by HIV, may be depleted and show marked dysfunction in antigen-presenting activity from an early stage of HIV infection. Natural killer (NK) cells and other cytotoxic cells show reduced recruitment and activity, in part due to reduced IL-2 and interferon γ production.

CD8 T lymphocytes are clearly altered in number with disease progression (see above) and show increased activation markers. Previously thought not to be infected, a recent report suggests that they may indeed be infected especially in patients with advanced disease, possibly as a result of infection of thymic precursors which coexpress CD4. This may contribute to the decline in their number in late disease and to their functional abnormalities. Furthermore, CD8 cells produce factors, which may include chemokines acting on the second receptor and/or other factors, that inhibit viral infection of CD4 cells. If these *in vitro* effects are operative *in vivo*, they may act to control or contain viral replication earlier in HIV infection. This is in addition to any role of CD8 cell-mediated specific cellular cytotoxicity, discussed above.

B cells show polyclonal activation in HIV-infected subjects, notably those with persistent generalized lymphadenopathy and Kaposi's sarcoma, with raised IgG1, IgG3, IgA, IgE and IgM levels. IgG2 and IgG4 levels may be low. Spontaneous immunoglobulin production is increased and responses to T cell-independent antigens are reduced. Enhanced B cell IgD production and raised serum IgD levels imply increased immaturity of B cells, which is also suggested by phenotypic alterations. In addition, responses to B cell mitogens and T cell-dependent mitogens and antigens are impaired, whether at a T cell level, antigen-presenting cell level, B cell level or a combination of any of these. Follicular dendritic cells in lymph nodes, which show evidence of HIV infection, show progressive destruction in patients with symptomatic HIV infection and AIDS. As a result of these various defects, patients show increased levels of antibodies to previously encountered antigens but are unable to develop new antibody responses.

The neuropathogenesis of HIV encephalopathy

and other nervous system disorders is more obscure. However, HIV encephalopathy also appears to result from both loss of cells and defective function of those that remain. The main cell type in the nervous system that harbours HIV is the macrophage, including perivascular macrophages and microglia, with little indication of infection of neuronal or glial elements. It is likely that HIV infection of such cells causes release of virus proteins or macrophage products, which in turn damage or alter the function of neighbouring nerve cells. gp120 can interfere with neuronal function in a similar way to that seen in lymphocytes, with activation of signal transduction pathways and raised intracellular calcium.

Treatment strategies in HIV disease

The AIDS pandemic has meant that large numbers of patients with severe immunodeficiency now require health care provision. Such patients need substantial specialist input from a wide variety of medical disciplines as well as a wider multidisciplinary team. Accessible and appropriate health care systems are being developed to cater for the various stages of HIV disease. Patients are increasingly involved in aspects of their care, notably in health maintenance (avoiding undernutrition, smoking, alcohol excess, and other cofactors). Specific therapies are of three types: treatment/prophylaxis of opportunist diseases, antiretroviral therapies and immunorestorative approaches.

Many of the opportunist infections are readily manageable, especially in the earlier stages of AIDS, with the use of specific antimicrobials and antitumor therapies. For many of the infections, maintenance therapy is required to avoid relapse. For some common infections, the use of antimicrobial prophylaxis offers considerable benefit, although there is often a trade-off of toxicity or drug hypersensitivity. Indeed drug hypersensitivity (type I and/or type III) to sulfonamides, antifungals and other drugs is notably more common in these immunodeficient patients. The increasingly effective use of antimicrobial treatment and prophylaxis has changed the clinical profile of disease, with deferral or elimination of some opportunistic events and decreased morbidity. However, it presents further challenges as more patients have more prolonged periods of severe immunodeficiency, leading to a greater proportion being affected by the less treatable infections and tumors, and new and more complex clinical events.

Antiretroviral therapy has developed rapidly in recent years. Zidovudine (AZT), a reverse transcriptase inhibitor and the first agent to show clinical efficacy, has had a significant impact when given as

monotherapy in AIDS and symptomatic HIV infection, reducing viral replication and hence reducing the rate at which disease progresses. This led to valuable increases in length and quality of life; improvement in HIV encephalopathy and reduction in its incidence are other notable benefits. Myelosuppression, gastrointestinal symptoms and a mitochondrial myopathy are seen, particularly at high doses, in patients with more advanced disease or where other drugs add to these problems. The benefit of zidovudine monotherapy seems on average to wane after some 2 years, whether due to its intrinsic limitations or the emergence of viral resistance. A logical approach to antiviral therapy would be to start treatment earlier, while the virus is active but when immune destruction is not so far advanced. With zidovudine alone, despite early encouragement, there is no general benefit in terms of clinical outcome. Zidovudine has, however, been shown to decrease vertical transmission if given to mothers during pregnancy and to the neonate.

Given the nature of the viral challenge, the use of combination therapies seems highly appropriate, with the objective of increasing efficacy and inhibiting the emergence of viral resistance, and possibly reducing toxicity. Initially this approach was focused on other nucleoside analogues, such as didanosine, zalcitabine, lamivudine and stavudine. Recent studies have shown the greater and more prolonged clinical efficacy of dual therapy with pairs of nucleoside analogs, confirming earlier studies showing their greater impact on CD4 count and on viral load. These therapies appear to offer some efficacy in earlier stages of infection, but the optimal timing is uncertain.

Two other major classes of antiretroviral agents have emerged – non-nucleoside reverse transcriptase inhibitors (NNRTI) (e.g. nevirapine, delavirdine, loviride) and protease inhibitors (e.g. saquinavir, ritonavir and indinavir). Triple combinations (e.g. two nucleosides and an NNRTI, or two nucleosides and a protease inhibitor) have an even more potent and durable impact on markers and, at least on early evidence, on clinical outcomes than two-drug regimens. Viral resistance appears to be more profoundly inhibited, which offers encouraging prospects for long-term efficacy. These more substantial effects raise the possibility of much earlier treatment, and some studies are exploring the effect of treating at or around the time of seroconversion.

Many issues still need to be resolved regarding antiretroviral therapy: optimal timing; optimal initial combinations; suitable means of monitoring patients on treatment; how these can inform decisions about if and when to change and, if so, what to change to;

and appropriate sequences of therapy. While some further approaches to antiviral treatment are being studied, the current portfolio of three classes seems likely to remain the core of treatment for some time, and there is a need to ensure that the armamentarium is deployed most effectively.

Among antiretroviral approaches that have been tried was the use of soluble CD4 or CD4 linked to an Fc molecule as a decoy for viral gp120. This looked promising *in vitro* and appeared not to interfere with cell function, but *in vivo* results were disappointing. This may be for a number of reasons, including the need to achieve very high levels to inhibit viral spread, the short plasma half-life of CD4 and the probability that much cell-to-cell transmission occurs directly, without a fluid phase.

Immunological approaches to therapy have been disappointing to date, although most were tried before effective antiretrovirals were available. Some are being re-explored in combination with antiretroviral therapy. Bone marrow transplantation has been generally disappointing, even when combined with antivirals. Several cytokines have been tried, including IL-2 and interferon γ , with some encouraging *in vitro* changes, and these are being tried with antiretrovirals. Immunostimulation has always been hard to achieve in reality and no clear agent of this type has been shown to be effective. One trial has shown that inosine pranobex (isoprinosine) may delay disease progression when given to asymptomatic patients, but other trials have not confirmed this; the mechanism of action is not clear.

Immunoglobulin therapy has proved helpful in patients, especially children, with antibody deficiency, by reducing problems with pyogenic infections. HIV antibody from asymptomatic subjects has been used as passive specific antibody therapy in a few studies but the results are not impressive and do not suggest that any effect is necessarily due to an antiretroviral mechanism; it is doubtful that passively acquired antibody will be any better than that produced actively in stemming viral replication and cell-to-cell transmission. Some have suggested that immunization with certain HIV antigens may be effective but such approaches may be subject to similar provisos; recent reports of therapeutic vaccines show no benefit with envelope glycoprotein or p24.

Vaccines

Extensive work is being done to develop vaccines against primary HIV infection. This work has utilised gp120 or other viral proteins and has employed a variety of viral and other vectors. Antibody and cytotoxic responses can be readily obtained, but

most work in animals shows that infection is not prevented or is restricted to a few strains. It remains unclear whether these problems reflect limitations of the immune responses obtained with such approaches or whether they reflect the fact that in most cases primary infection of target cells occurs at the mucosal level, where contact between virus and macrophage or lymphocyte is unlikely to be impeded by such antibody as reaches that site. Some studies have examined ways of producing more substantial mucosal immunity and this would seem a critical element in any vaccine approach. The prospect of an effective vaccine in the imminent future seems remote.

ACQUIRED IMMUNE RESPONSE

Anne Sperling, Committee on Immunology, the Ben May Institute, University of Chicago, Chicago, Illinois, USA

Jeffrey A Bluestone, Department of Pathology, University of Chicago, Chicago, Illinois, USA

The development of immunity to a particular pathogen occurs after initial exposure to the antigen. The immunity is due to the development of an acquired immune response to the pathogen. A baby is born virtually immunologically naive. Maternal antibodies that have crossed the placenta provide transient protection from infection until the newborn's own immune system has developed sufficiently to mount

an immune response strong enough and fast enough to protect against initial infection. After a primary immune response to a pathogen, an acquired immunity is developed such that any further infection by that pathogen is immediately controlled. The secondary or acquired immune response to the pathogen is more rapid and of greater magnitude and thus provides elevated protection against infection. From

birth throughout a person's life, the immune system is continually responding to new environmental challenges (e.g. bacteria and viruses), and developing immunity to those challenges. The study of the acquired immune response is the basis of the science of immunology.

Historical background

The phenomenon of acquired immunity was observed as early as 430 BC when the historian Thucydides in his description of the plague of Athens wrote: 'Yet it was with those who had recovered from the disease that the sick and the dying found most compassion. These knew what it was from experience, and had now no fear for themselves; for the same man was never attacked twice – never, at least, fatally.' Thus even the early Greeks understood that individuals who had been exposed to a disease were provided protection from later susceptibility.

In the eighteenth century, the practice of active immunizations by inoculation with diseased material from smallpox victims (or later the inoculation of related or attenuated virus discovered by Jenner) was the impetus for modern studies of the acquired immune response. Today the acquired immune response is still being investigated on both the cellular and the molecular level.

Characteristics of the acquired immune response

The first time an antigen enters the body a wide spectrum of events occurs. The antigen is usually contained at the site of entry and in nearby lymph nodes by various phagocytic cells such as macrophages and dendritic cells. These cells process the antigen and present pathogen-derived peptides to CD4⁺ and CD8⁺ T cells in association with major histocompatibility complex (MHC)-encoded molecules. Antigen binding by surface immunoglobulin and cognate help by CD4⁺ T cells induce B cells to differentiate to antibody-secreting plasma cells. During a primary immune response there is a lag time of approximately 3–4 days before antigen-specific antibody is evident in serum, and the levels do not peak until approximately day 7. The antibodies produced are primarily immunoglobulin M (IgM), which are characteristically very heterogeneous in their affinity for the antigen. IgG antibodies do not appear in the serum until approximately day 7 and do not peak until day 14. Thus the primary humoral immune response is very slow and weak.

The acquired or secondary immune response occurs when the antigen is encountered by the

immune system any time after the primary response. This may occur several days or many years after the initial encounter. The acquired response is characterized by a more rapid and intense attack by the immune system. Increased levels of IgG antibodies appear in the serum within 24 h after infection. In the case of cell-mediated immunity, greater numbers of antigen-specific T cells rapidly respond. The ability of the immune system to 'remember' past exposure to antigens is called immunological memory and is one of the hallmarks of the immune system.

Mechanisms of acquired immunity

Development of high-affinity memory B cells

Towards the end of a primary response, higher affinity antibodies are found than were apparent early on. This phenomenon is called affinity maturation, and is found primarily with antibodies derived from B cells that have undergone isotype switching to IgG or IgA classes. During the primary response, many of the B cells differentiate to memory B cells. These memory B cells have been found to be extremely long-lived and, when activated, characteristically produce immunoglobulin that is similar to that found during the later stages of the primary response. Thus, when antigen is encountered by memory B cells, the cells are easily activated and able to produce a strong and rapid humoral immune response.

Memory B cells are highly effective antigen-presenting cells

The clonal expansion of antigen-specific memory B cells provides a large population of highly specific antigen-presenting cells. It has been shown by several groups that antigen-specific B cells are much more effective presenting cells than other known accessory cells such as macrophages and dendritic cells. Memory B cells take up antigen through their high-affinity surface immunoglobulin, and present high concentrations of antigen in association with MHC on their surface. Thus, antigen presentation to T cells, a critical early event in generating an immune response, is also more effective during a secondary immune response.

Clonal expansion of antigen-specific T cells

During the primary immune response, antigen-specific T cells are clonally expanded. It is believed that this expansion provides a further level of protection from reinfection. The mechanisms involved in the development and maintenance of T cell memory are

still unclear. After the initial T cell expansion, the antigen-specific T cells are downregulated through induction of programmed cell death and anergy. This stage is followed by the development of an antigen-specific memory T cell population. This population of T cells can remain with the individual for a lifetime, and can provide protection from further infections by the organism that expresses the antigen. There are two proposed mechanisms for how the body maintains these antigen-specific memory T cells. The first is that once these memory cells develop, they are extremely long-lived and can survive indefinitely to provide protection for the individual. The second hypothesis is that a small but significant amount of antigen persists in the individual. This antigen-persistence provides a continual level of stimulation for these memory T cells and is able to stimulate the production of new memory T cells.

Antigens that do not induce acquired immunity

Interestingly, not all antigens induce immunological memory. The best studied of these are T-independent (TI) antigens. TI antigens are capable of stimulating B cell proliferation and differentiation in the absence of cognate T cell help. Common TI antigens are polysaccharides and polymers, both of which are composed of highly repetitive subunits. The reason that these antigens are unable to effect an acquired immune response is still unclear. However, it is known that TI antigens tend to stimulate a subset of B cells, CD5⁺ cells, that may not be capable of differentiating into memory cells.

Medical indications of the acquired immune response

Clearly the most impressive medical indication of the

acquired immune response is vaccination. The simple and elegant theory of vaccination is that induction of a primary immune response by a nonpathogenic form of an antigen leads to immunity of the infectious form. Common types of vaccines are attenuated pathogen, related noninfectious antigen, and purified proteins from the pathogen. Examples of all of these vaccines have been used to induce a primary immune response that confers acquired immunity.

ACUTE INFLAMMATORY REACTION

Sanna Rosengren, Department of Immunology, Gensia Inc., San Diego, California, USA

The acute inflammatory reaction constitutes the first line of defense against infection as well as the initial stage in restoring injured tissue to normalcy. Acute inflammation is recognized by redness, swelling, heat and pain in the affected area. These symptoms stem from a multitude of events taking place within the inflamed site. The humoral arm of the immune response, including circulating antibodies and the complement system, is activated. Leukocytes which normally travel within the bloodstream recognize signs of tissue in distress, adhere to and traverse the

blood vessel wall and migrate toward the source of irritation. The permeability of small venules increases, leading to edema formation, and furthermore the blood flow through inflamed tissue is altered as a result of modification of arteriolar tone. Additionally, a multitude of cell types are activated to liberate various inflammatory mediators, including cytokines and arachidonic acid metabolites, which in turn can affect every aspect of inflammation mentioned above. The intricacy and complexity of the inflammatory reaction cannot be underestimated

and the detrimental impact of these events on normal function is often massive.

Cause of inflammation

While a classical immune response can elicit acute inflammation, both through antibody–antigen complex formation and through activation by cytokines secreted by T cell activated macrophages, the focus of this entry will be on effector cells such as neutrophils and endothelial cells. Signs of acute inflammation are seen in connection with infection by various pathogens, but tissue injury induced by physical, chemical or thermal means, without infection of foreign bodies *per se*, will also induce an inflammatory response. Additionally, a host of mediators, some of them listed in Table 1, will induce inflammation upon injection.

A particularly important clinical problem is the inflammatory response followed by tissue injury which is associated with ischemia/reperfusion situations such as myocardial infarction, stroke or transplantation of organs. Another example of an inflammatory response gone awry is the systemic inflammatory response syndrome (SIRS) sometimes seen in connection with systemic infection, extensive burns, ischemia, trauma or hemorrhagic shock. These conditions highlight the importance of understanding the inflammatory reaction for the purpose of adequate clinical intervention.

Table 1 Some inflammatory mediators and their actions *in vivo*

Mediator	Neutrophil accumulation	Edema formation ^a
Histamine		x
Bradykinin		x
Serotonin		x
Complement factor C3a		x
Complement factor C5a	x	x
PGD ₂ , PGE ₂ , PGI ₂		x ^b
LTC ₄ , LTD ₄ , LTE ₄		x
LTB ₄	x	
PAF	x	x
TNF α	x	
IL-1	x	
IL-8	x	
Substance P	x ^b	x

PG, prostaglandin; LT, leukotriene; PAF, platelet activating factor; TNF α , tumor necrosis factor α ; IL, interleukin.

^aIncludes mediators that induce edema through direct action on endothelium only.

^bIn some models only.

The neutrophil granulocyte

Mechanisms of neutrophil infiltration

The first leukocytes to infiltrate a site of inflammation are neutrophil granulocytes, which sometimes begin to accumulate within minutes of induction of inflammation. A host of adhesion molecules essential for neutrophil recruitment have been identified. During its journey through the vasculature, the neutrophil makes transient contact with the vascular wall of postcapillary venules, which gives the cell a rolling motion across the endothelium. This phenomenon is dependent on L-selectin (CD62L), present on the neutrophil surface, which recognizes and binds carbohydrates on the luminal surface of the vascular endothelium. Near an inflammatory site, however, the neutrophil becomes activated, the L-selectin is shed from the surface, and now the CD11b/CD18 adhesion complex, part of the integrin family, comes into play as the neutrophil adheres firmly to the vascular wall. Next, the neutrophil migrates out of the vessel through the junction between adjacent endothelial cells, and continues to move through the tissue toward the inflamed area, guided by inflammatory mediators which form a chemotactic gradient.

Other selectins, P- and E-selectin (CD62P and CD62E, respectively), can be found on the endothelial surface after stimulation with certain inflammatory mediators. P-selectin appears within minutes, whereas E-selectin is first found some hours after stimulation. Both P- and E-selectin can support neutrophil rolling along the endothelium together with neutrophil L-selectin.

An interesting exception to this scenario is seen in the lung. The low pressure in the pulmonary circulation combined with the narrow dimensions of lung capillaries leads to occasional trapping of neutrophils in these vessels, a phenomenon referred to as 'plugging'. When activated, neutrophils become stiffer as a result of intracellular actin polymerization, facilitating capillary trapping which may take place independently of the above-mentioned adhesion proteins. The cells may then migrate from the capillaries, which appear to be the main site for neutrophil extravasation in the lung. Plugging is also seen in some ischemia/reperfusion models, and has been suggested to account for the no-reflow phenomenon after severe ischemia, although this remains controversial.

Tissue injury by neutrophils

The neutrophil contains a formidable arsenal of proteinases, lysozyme and oxygen radical-forming enzymes in its granules, usually employed to

kill microorganisms ingested by the neutrophil. Occasionally, however, these injurious products may be released to the extracellular space and cause tissue damage, for example if the perceived foreign body is too large for ingestion. In addition, antiproteinases normally present in the interstitial fluids can be inactivated by neutrophil-derived oxygen radicals, thereby enhancing the damage inflicted by neutrophil proteinases such as elastase, gelatinase and collagenase. Experimental proof for neutrophil-inflicted tissue injury is found in models of immune complex-induced dysfunction of various organs such as the Arthus reaction and nephrotoxic nephritis, among others.

Vascular leakage

Tissue swelling is one of the most obvious signs of inflammation. It is generated by an increase in vascular permeability to plasma proteins and fluid. Under normal conditions the endothelial layer lining blood vessel walls is relatively nonpermeable to proteins and other molecules above 30 Å, and the small exchange between the intravascular and extravascular compartments occurs by transport through the endothelial cell bodies as well as through junctions between adjacent endothelial cells. During inflammation the endothelial cells in small venules retract from each other after cell junctions, in the form of cadherins, break apart. This results in large pore formation and massive exudation of plasma proteins. Many inflammatory mediators, including histamine, bradykinin, certain complement factors and serotonin, can act directly on the endothelial cells to cause retraction, although the exact underlying mechanism is yet to be described. This is partly due to the difficulty in studying these events in *in vitro* cell culture.

In some experimental models of inflammation the observed edema is dependent entirely on neutrophil infiltration. Many of the products liberated from activated neutrophils increase the permeability of vascular walls by causing endothelial damage. In some cases, however, neutrophils cause edema without apparent dependency on its proteases or oxygen radicals and in the absence of evidence of injury to the vessel wall. The migration through endothelial junctions by neutrophils could theoretically be enough to open a gap between endothelial cells. An alternative explanation is found in the multiple

polycationic proteins present in neutrophil granules, which can cause endothelial retraction through a poorly understood charge interaction with the endothelial surface. In a fulminant multifactorial inflammatory response, however, all of these mechanisms are likely to contribute to the observed edema.

Concluding remarks

The acute inflammatory reaction stems from a complex and interdependent set of events at the microvascular level which lead to the easily recognizable symptoms of inflammation: redness, swelling, heat and pain. Depending on the situation, it can constitute a necessary defense against a potentially threatening invasion of pathogens, or it can itself be a threat to the organism because of the destruction of tissue taking place in the process. A better understanding of the relative importance of the various mediators and cell types involved is crucial for successful therapeutic intervention in inflammatory disease.

ACUTE PHASE PROTEINS

Mark B Pepys, Immunological Medicine Unit, Royal Postgraduate Medical School, Hammersmith Hospital, London, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Acute phase proteins are plasma proteins, the synthesis and the circulating concentrations of which are adaptively regulated in response to most forms of inflammation, infection and tissue injury. The name arises from the fact that the first such protein, C-reactive protein (CRP), was originally discovered in serum of patients in the acute phase of pneumococcal pneumonia. However, it soon became apparent that increased levels of CRP and certain other plasma proteins occurred during active, tissue-damaging disease processes, whether acute or chronic. Nevertheless the term 'acute phase' has persisted and is in general use to describe a large group of disparate plasma proteins (Table 1) which share the property of increased production after injury and in disease states. A small number of proteins, including albumin, the single most abundant plasma protein, show the reverse pattern and are called 'negative acute phase proteins' because their levels fall during the acute phase response (Table 1).

Table 1 Plasma protein concentrations in the acute phase response

	Increased	Decreased
Proteinase inhibitors	α_1 -Antitrypsin α_1 -Antichymotrypsin	Inter α -antitrypsin
Coagulation proteins	Fibrinogen Prothrombin Factor VIII Plasminogen	
Complement proteins	C1s C2, B C3, C4, C5, C6 C9 C1 INH	Properdin (P)
Transport proteins	Haptoglobin hemopexin (Ceruloplasmin)	
Lipoproteins		High density lipoprotein Low-density lipoprotein
Miscellaneous	C-reactive protein Serum amyloid A protein α_1 -Acid glycoprotein Gc globulin Ceruloplasmin (Fibronectin)	Albumin Prealbumin (Transthyretin)

The acute phase proteins include members of the coagulation and complement systems, proteinase inhibitors and transport proteins, as well as several proteins of unknown function. The response as a whole, and many of the individual proteins, are conserved among endothermic animals and it therefore seems likely that it has an overall beneficial effect, possibly related to minimizing tissue injury, enhancing host resistance and promoting resolution of inflammation and repair. However, the whole, essentially nonspecific, phenomenon of the acute phase response is very complex and forms part of an even wider response to viable or nonviable noxious stimuli, involving fever, the immune system, the hematopoietic system, the stress-related endocrine system and protein, lipid and carbohydrate metabolism both locally and generally.

Synthesis of acute phase proteins

Most acute phase proteins are synthesized in the liver, although the genes for some are also expressed in cells and tissues elsewhere. Transcriptional control is the main mechanism for regulation of production but mRNA stability contributes in some cases. A large number of cytokines, including interleukin 1 (IL-1), IL-6, tumor necrosis factor α and various interferons, are capable of inducing increased, or in some cases decreased, production of various acute phase proteins *in vivo* and in cultured hepatocytes and liver cell lines *in vitro*. Glucocorticoids and steroid sex hormones can play an important permissive role and neural and neuroendocrine influences may be significant *in vivo*. Results obtained in different laboratories with different acute phase proteins, different cytokines and different cell lines or experimental systems have shown much variation. It has been difficult to reconcile all the findings and to identify the critical participation of particular mediators in control of particular reactants, especially because of the cascade effects by which some cytokines promote the production of others. Nevertheless it is striking that IL-6 knockout mice mount absolutely no acute phase response of serum amyloid A protein (SAA), serum amyloid P component (SAP) or complement component C3 following induction of sterile inflammation by casein or silver nitrate injection, whereas lipopolysaccharide (LPS) induces a definite, although subnormal, response.

Studies with transgenic mice bearing the human CRP gene, with transfected cells containing human SAA genes, and with hepatoma cell lines, have identified regulatory flanking regions of DNA which are targets for the action of nuclear factors responsive to IL-6 and IL-1.

Diversity of acute phase proteins

There is considerable diversity among acute phase proteins with respect to the concentrations attained, their structures, their behavior in different species and in different diseases. The concentration of a plasma protein depends on the balance between its secretion rate and its clearance rate. The availability of the protein for a particular function is the important factor in physiological and pathophysiological situations, rather than simply its serum concentration measured *ex vivo*. Increased availability can exist by virtue of increased production and yet be disguised by increased utilization or clearance so that plasma levels are normal or even decreased. Definition of acute phase proteins solely on the behavior of their plasma levels, while easy and convenient, is thus superficial and clearly misses important patterns of metabolic regulation of plasma proteins.

Among the acute phase proteins the increases vary between one- and twofold, for example, for some complement components, through up to five- to tenfold, for example for some clotting factors and proteinase inhibitors, and up to 1000-fold or more for CRP and SAA. CRP and SAA are trace constituents of normal plasma and are the most dramatic acute phase reactants increasing very rapidly to peak levels which may be up to 3000 times normal at about 48 h after an acute event. Persistently high levels may occur in chronic active disease processes, but with effective therapy or spontaneous resolution they fall to normal with a half-time as fast as 24–30 h. In contrast, all other acute phase proteins respond more slowly, taking days to reach their peak values, and also falling much more slowly, reflecting clearance and catabolic half-lives of days rather than hours. Furthermore, unlike most other acute phase proteins, there seems to be little effect of disease processes on the clearance or catabolism of CRP and SAA. The synthesis rate, which reflects the intensity of the pathology which induced their production, is thus the most important or even sole determinant of their plasma levels. For all these reasons these two acute phase proteins are the most useful for clinical purposes in humans.

Acute phase proteins are structurally extremely diverse. Most are glycoproteins produced predomi-

antly, though not exclusively, by hepatocytes. The extent and heterogeneity of glycosylation is often significantly increased during the acute phase response, apparently under the influence of the stimulatory cytokines. However, CRP and SAA are not glycosylated. SAA, unlike all the other acute phase proteins, is an apolipoprotein associated with high density lipoprotein, and unlike CRP, which shows no polymorphism, SAA is highly polymorphic. There are several sets of genes for SAA, including some which are predominantly expressed in tissues other than liver and the products of which are not significantly present in the plasma. There are also differences in the responses of different SAA genes to different acute phase stimuli. The importance of this diversity is not clear since the normal function of SAA, and its role in acute phase situations, are not known. However, SAA is the precursor of AA protein which forms the fibrils in reactive systemic, AA-type amyloidosis, a serious and usually fatal complication of chronic persistent infections and inflammatory disorders.

While the profile of acute phase plasma proteins is broadly similar across species there are nonetheless important differences. For example, SAP is a major acute phase reactant only in the mouse, and there are many other differences in normal levels and acute phase behavior of other members of the pentraxin family of proteins to which it belongs. While these differences may be important for the usefulness of particular proteins as markers in clinical or experimental situations, they may not reflect, as has been pointed out above, the underlying metabolic regulation. On the other hand, some species differences are clearly of physiological and pathophysiological importance. Thus, although rats have a gene for a homolog of SAA, the expression of which is regulated as an acute phase protein, the product does not appear as a plasma lipoprotein and rats never get AA amyloidosis. This contrasts with the behavior of SAA in all other mammals and birds which have been studied.

Finally, even within a species there is diversity in the acute phase response to different stimuli, to different disease processes and between different individuals. This has been most extensively studied in the case of CRP and SAA responses in humans, in whom there is a small number of serious inflammatory or tissue-damaging disorders characterized by absent or minimal acute phase production of these proteins. These exceptional disorders include systemic lupus erythematosus, dermatomyositis, Sjögren's disease, scleroderma, ulcerative colitis and leukemia, in all of which only a minority of patients have more than modest elevations of CRP or SAA concentration,

even in the face of extensive and active disease. Other acute phase proteins are produced, apparently normally, and if these patients acquire a significant intercurrent infection they then mount major acute phase responses of CRP and SAA. These phenomena are of considerable clinical value but the underlying mechanisms, whether of macrophage response, cytokine production or hepatocyte response are not known. In the great majority of other diseases in which CRP and SAA levels are greatly increased, the levels attained closely reflect the extent and activity of the pathological process in each individual, and serial monitoring provides valuable objective and quantitative information about the natural history of the disorder or its response to treatment. However, while there is usually a good general correlation between disease activity and CRP/SAA concentration there may nonetheless be considerable variation between the acute phase protein levels seen in different individuals with apparently comparable degrees of clinical activity. These variations are due partly to difficulties in clinical assessment of disease activity but mostly to genuine interindividual differences in the acute phase response.

Biological and clinical importance of acute phase proteins

Acute phase proteins and the response in general are stably conserved in evolution and are universal within each species. They are thus presumably of benefit to the organism undergoing infection, inflammation and/or tissue damage, although much remains to be learned of the properties and functions of many acute phase reactants. On the other hand, sustained, increased production of SAA is a necessary though not sufficient condition for the development of reactive, systemic AA amyloidosis, a grave complication of chronic infection or inflammation. Monitoring of the acute phase response, particularly by measurement of CRP in man, CRP or SAA in other species, and SAP in the mouse, is a powerful and

sensitive test for organic disease or the toxicity of an administered agent. It also provides the most accessible means for objective, quantitative assessment of disease extent and activity, and is valuable in the differential diagnosis of intercurrent infection especially in the immunocompromised host.

The application of new high sensitivity immunoassays for CRP in studies of atherosclerosis has lately revealed very important prognostic associations between previously undetected low grade acute phase responses and the progression and complications, especially of coronary heart disease. These findings open up a new area of considerable fundamental interest and clinical significance, relating mild chronic inflammation to the most common cause of death in the developed world.

ADENOVIRUS, INFECTION AND IMMUNITY

Liise-anne Pirofski and **Marshall S Horwitz**, Departments of Medicine, Microbiology and Immunology, Albert Einstein College of Medicine, New York, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Adenoviruses (Ad) are highly species-specific icosahedral DNA viruses. Multiple Ad serotypes cause a variety of clinical syndromes in humans including respiratory, genitourinary, gastrointestinal and conjunctival infections. Ads are relatively resistant to conventional antiviral chemotherapy, though a highly effective oral Ad vaccine has been used to prevent acute respiratory disease (ARD) in the military population. The human immune response to Ad infection is characterized by the development of serotype-specific neutralizing antibodies to Ad structural proteins which prevent reinfection with the same serotype. In addition, Ad genomes are characterized by four transcription groups that lead to the production of early (E) nonstructural proteins which exert important immunologic effects. The E3 region is not essential for viral replication and can be replaced with foreign DNA. Ad vectors for the delivery of foreign genes have been developed for immunization against non-Ad infections and for gene therapy. Achieving the long-term expression of foreign Ad-inserted genes and abrogating host immune responses that lead to rejection of delivered genes are active areas of research.

Adenoviruses were first isolated by Rowe and Hartley in 1953 when cytopathology was noted serendipitously in cultures of human tissue removed during tonsillectomies and adenoidectomies. Although the first Ad isolates were from patients without acute infectious symptoms, it was recognized subsequently that Ads were associated with a group of respiratory and ocular syndromes. Some of these diseases, such as conjunctivitis, had been known as distinct clinical entities for almost a century before the first isolation of Ads. The number of unique Ad serotypes proliferated and now there are at least 49 distinct types that are currently recognized by neutralization reactions. The Ads are classified into six subgroups (A–F) based on criteria which include the patterns of hemagglutination (HA) of a variety of species of red blood cells. Cross-hybridization of the Ad DNA genomes is greater than 50% for agents within a single sub-group. The discovery by Trentin in 1962, that Ad 12 was highly oncogenic in hamsters, began an era of excitement and uncertainty as attempts were made to link Ads and other DNA viruses with human tumors. All these efforts failed to reveal any reproducible association between

Ads and human malignancy. However, molecular biologic studies of the mechanism of Ad transformation have provided a paradigm for understanding virus-mediated transformation in general.

As a parallel development to the studies of Ad oncogenesis in model systems, investigators were exploring the use of Ad vaccines to prevent acute respiratory disease (ARD) in military recruits as they entered a new epidemiologic environment (see below). The first batches of inactivated Ad vaccine were contaminated with live simian virus-40 (SV40), an unknown virus at the time. The helper effect of SV40 on Ad growth in monkey cells was discovered during these studies.

Ads cause upper respiratory tract infections (URI) and pneumonia. Serotypes 8, 19 and 37 are associated with severe conjunctivitis. Ad infections of the urinary tract due to types 11 and 21 may produce hemorrhagic cystitis, especially in males. Ads 40 and 41, which induce gastroenteritis, are more difficult to grow in conventional tissue culture systems such as human embryonic kidney (HEK) and require special cells such as HEK 293 transformed by the Ad5 early region E1 for propagation. Other Ad serotypes cultivatable from enteric sources have not been reproducibly associated with diarrhea even though they may be persistently shed.

Characteristics of the organism and its antigens

The Ads of different serotypes have an icosahedral architecture, a double-stranded linear DNA, and more than 12 structural proteins, three of which are major components of the capsid (**Figure 1**). There is no virus envelope; 240 hexons, each a trimer of identical polypeptides, are the major subunits of the 252 capsomere shell with 12 different structures called pentons at each of the vertices. The penton is composed of five penton base and three fiber polypeptides which project out from the base in an antenna-like structure. These polypeptides are antigens for host immunologic responses to natural and vaccine-associated infection. The internal structural proteins are divided into those associated with the DNA in a core-like structure and others that bind to the inner surfaces of the hexon or penton capsomeres. None of the internal proteins appear to be involved in humoral or cell-mediated immunity.

Figure 1 Schematic representation of an adenovirus. The mobilities and relative amounts of each protein after electrophoresis of the dissociated virus on a sodium dodecyl sulfate-containing polyacrylamide gel are shown on the right. The position of each polypeptide in the virion is designated (modified from Horwitz, M.S. (1990) *Adenoviruses and their Replication in Fields' Virology*, 2nd edition, pp. 1679–1721, Raven Press, edited by Fields, et al.

Several nonstructural proteins that are made early after infection have immunologic significance. These early proteins are the products of four transcription groups: the E1A, E1B, E3 and E4 genes have all been postulated to exert important immunologic effects. Both the E1A and E3 regions affect the expression of class I major histocompatibility complex (MHC)-encoded proteins on the cell surface. In model systems *in vivo* and *in vitro*, the E1A gene of Ad12 (which together with the E1B gene is responsible for transformation by the oncogenic Ads), has been shown to inhibit transcription of the class I MHC. This mechanism appears to be limited to the highly oncogenic Ads. In most of the other Ad serotypes that have been studied, a 19 kDa glycoprotein (E3-19 kDa) product of the E3 region has been demonstrated to bind tightly to the class I MHC heavy chain in the endoplasmic reticulum and prevent transport of this complex to the cell surface. Thus, the Ads have evolved two mechanisms to regulate cell surface MHC. The E3 region, which contains 10% of the Ad-coding sequence, includes other genes whose products may have immunologic significance. There is a 14.7 kDa protein and a heterodimer of 10.4/14.5 kDa that inhibit tumor necrosis factor (TNF) lysis of Ad-infected cells. The 14.7 kDa protein does not inhibit TNF by interacting with the ligand or its receptor: it exerts its effect intracellularly by inhibiting the cell death pathway. The details of this process are unknown, though 14.7 kDa inhibits TNF-induced release of arachidonic acid.

Four 14.7 kDa interacting intracellular proteins have been isolated recently; one of them, FIP-1, is a small GTPase with homology to members of the ras family. The 10.4 kDa protein also promotes the internalization of both the epidermal growth factor (EGF) and insulin receptors by a mechanism that is currently unknown. The biological importance of these proteins *in vivo* is under active investigation. For example, the entire cassette of E3 proteins has been expressed as a transgene in mice behind the rat insulin promoter. The E3-transgenic islets can evade the immune system in both allogeneic transplantation and autoimmune diabetes models. Recently, it has been shown that the Ad E3 that is overexpressed in rats by replication-defective Ad vectors used for gene therapy can suppress the humoral immune response to the virus. The E3 genes responsible for this effect and their mechanism of immunomodulation are under investigation.

Another nonstructural gene, VA-1, produces a transcript using RNA polymerase III. This transcript is not known to code for any protein, but the VA-1 can inhibit the action of interferon-induced phosphorylation and allow protein synthesis to continue in Ad-infected cells.

The Ad structural proteins – hexon, fiber and penton – are the antigenic determinants for both group- and type-specific antibodies. The fiber is the major attachment protein but entry is facilitated by the penton base protein. Adenovirus types 2 and 5 fibers bind through the terminal knob to a common recep-

tor shared with the coxsackie B viruses, but have also been reported to bind to class I MHC molecules. The penton base binds to both the $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins. The α determinant demonstrable on hexon is a cross-reacting group antigen found on most of the known human and animal Ads. The ϵ determinant of hexon and the γ determinant of fiber both give rise to type-specific neutralization (Nt) antibodies. Some of these determinants have now been mapped to specific nucleic acid sequences. Classically, type-specific antibodies have been detectable by hemagglutination inhibition (HAI), and Nt assays. Ad neutralization is serotype specific and generally demonstrable only with homologous antisera. However, some heterologous sera are capable of neutralizing virion at low pH (pH 5.5). Neutralizing antibodies recognizing the Ad hexon of serotypes 1–5 and the Ad fiber of types 1, 2 and 5 have been extensively studied in animal models. Antibodies against fiber can induce virion aggregation though virus attachment to host cells is facilitated by this mechanism. However, such aggregated Ads do not uncoat or enter the cytoplasm for eventual transport along microtubules to the nucleus. Although neutralization parallels aggregation, another mechanism for virus neutralization apparently occurs by antibody-mediated inhibition of viral entry from acidic vesicles into the cytoplasmic compartment. A similar mechanism has also been described for antibodies to penton base which also appear to inhibit by a mechanism independent of virus aggregation. Complement fixation or fluorescent antibody (FA) tests generally detect the presence of group-specific antibody, whereas HAI and Nt assays determine the serotype and the existence of serotype-specific immunity. In addition, type-specific monoclonal antibodies against Ads 40 and 41 can be used with FA, latex agglutination or ELISA assays to distinguish these enteric serotypes from others that are shed in the gastrointestinal tract as a component of Ad infection of the respiratory tract. Immunologic assays and other techniques such as nucleic acid hybridization, quantitative electron microscopy, direct Ad genomic DNA restriction endonuclease profiles of nucleic acid in stool specimens, and polymerase chain reaction (PCR) with selected serotype-specific primers are facilitating the diagnosis of Ad-related gastrointestinal and other clinical syndromes.

Immune responses of the host

Adenovirus infections are followed by serotype-specific immunity which is most likely mediated by serum-neutralizing antibodies. These antibodies protect against reinfection with the same serotype,

though asymptomatic viral shedding from tonsillar epithelium, lymphocytes and enteric epithelium may occur for many months in the presence of neutralizing antibodies. The role of cell-mediated immunity in recovery from acute infection and prevention of reinfection is not understood. Proteins encoded in the E1A or E1B regions are major targets for both cytotoxic T lymphocytes (CTLs) and for natural killer (NK) cell responses. CTLs have been induced in mice inoculated with human Ads.

Animal models of human Ad infection are imperfect because these viruses are highly species specific. In most species, human Ad infections result in abortive infections in which early viral genes are expressed. However, adenovirus infection of the cotton rat produces progeny virus and causes an inflammatory response in the lungs after intranasal infection. The effect of the E3 genes has been studied after intranasal infection of both cotton rats and mice with adenovirus E3-deletion mutants. Deletion of three anti-TNF genes (E3 14.7 kDa, 10.4 kDa and 14.5 kDa) resulted in worsening of pulmonary pathology as evidenced by the conversion of a mononuclear to a polymorphonuclear response in the peribronchial area of the cotton rat lung and the increase of alveolar inflammation in the mouse lung. The pulmonary response to deletion of gp19kDa was discrepant in that the inflammatory response increased in the cotton rat but was unchanged in the mouse.

Adenovirus infections are not as common as infections with members of the herpesvirus group in immunocompromised hosts. However, patients with various malignancies or following cytotoxic therapy have had more severe and more frequent episodes of Ad disease. Liver transplant patients in the pediatric age group have had fatal infection due to the ubiquitous Ad5 serotype. Patients with the acquired immune deficiency syndrome (AIDS) have had persistent infections with various Ad serotypes. Group B Ads 34 and 35 have been isolated chronically from the urine of many AIDS patients. Group D agents have been persistent in the stools of other AIDS patients studied. Both of these patient groups appear to be asymptomatic from their genitourinary or gastrointestinal tract Ad infections. Adult AIDS patients infected with Ads 34 and 35 do not make serum antibodies against these viruses though most of these patients had antibodies against Ad2, a serotype that they most likely acquired before HIV infection. The target of the major neutralizing antibodies against Ad35, the fiber gene, manifested changes from the prototype in many Ad35 isolates from AIDS patients. There appeared to be intermolecular recombination between genomes that were primarily Ad34 or 35 by restriction endonuclease analysis, but

that had the fibers characteristic of other group B Ads such as Ad 3, 7, 11, 16 and 21. Recombination between serotypes within the Ad subgroups is known to occur both in tissue culture and *in vivo*, though there was no evidence that the intermolecular changes, thought to occur by recombination, had arisen during chronic carriage of these Ads in any of the patients studied. This conclusion was reached by examining serial isolates over many months and finding that the serologic reactivity as well as the restriction endonuclease patterns of each Ad isolate had not changed during this period of observation. Thus, the frequency of these important antigenic changes is uncommon in each chronically infected individual.

Vaccines

Historically, the development of Ad vaccines provided new insights into important issues regarding the determination of the safety and efficacy of live viruses for disease prophylaxis. The development of an Ad vaccine became a major priority in the early 1960s after the realization that Ads were responsible for most of the ARDs in up to 80% of American military recruits (who often required hospitalization). Types 3, 4, 7, 14, and 21 Ads caused most of the disease in military recruits and trials of the first vaccines took place between 1958 and 1962. The initial vaccines consisted of inactivated whole-virus strains. However, besides not being completely effective, it was discovered that the seed stocks of vaccine virus were contaminated with fully viable SV40 as noted above. SV40 actually functioned as a helper virus that was essential for the replication of both Ad4 and Ad7. It was realized then that Ad grew in monkey kidney tissue culture only because many of these cells were contaminated *in vivo* by SV40 which produced a T antigen that complemented the Ad replication defect in cells of simian origin. Attempts to rid the Ad seed stocks of SV40 by the use of antibodies against the latter virus were responsible for promoting the intermolecular recombination of portions of the SV40 T antigen gene with the Ad genome. The resulting Ad-SV40 hybrid viruses were shown to be more oncogenic than Ad alone in various rodent species, though extensive studies have failed to show any oncogenic effect of these hybrid viruses in humans inadvertently inoculated with them during the early field trials of Ad vaccines. With increased knowledge of the biology of Ads, a live vaccine free of SV40 genes was formulated against Ads 4 and 7 for use in the military. Despite the anticipation that other respiratory

Ad strains would need to be included as vaccination programs proceeded, this has not been the case.

The adenovirus vaccine currently in use is an enteric coated tablet that protects the host from respiratory infection. It contains Ad 4 and 7 strains adapted for growth in human embryonic fibroblast (W1-38) tissue culture. Vaccine amounts of greater than 10^4 tissue culture infection dose₅₀ (TCID₅₀) in a single administration protect at least 95% of vaccinated recruits. Some individuals develop neutralizing antibodies without evidence of infection, although the vaccine infection rate is greater than 90% as measured by fecal excretion of vaccine Ad strains. In contrast to natural infection, Ad vaccine-induced neutralizing antibodies are not secretory IgA. Nonetheless, the vaccine is highly protective. It must be given within 2 h of the recruit's arrival at the training base because vaccine-mediated protection does not occur during the incubation period of wild-type Ad infection. The adenovirus vaccine strains are safe and are not oncogenic: since the introduction of the vaccine in 1965 it has been administered to over 10 million people.

Ad infections in children cause 5–10% of all pediatric respiratory infections. Since children are infected with other serotypes such as Ads 1, 2 and 5, it was anticipated that the adult vaccines would be reformulated to include these serotypes. However, Ad vaccines for civilians and children are not presently available. Ad vaccination of children has lagged behind the successful efforts to protect the military population because of some uncertainties about the initial safety of the vaccines, and the present enteric formulation which requires swallowing the vaccine tablet intact.

Adenoviruses as vectors for the delivery of foreign genes

Ads have been developed as vectors for the delivery of foreign antigens for immunization against other (non-Ad) infectious agents and for gene therapy. Ads are good vectors for the delivery of foreign DNA in that viral replication is not dependent upon host cell replication, they can be molecularly engineered to enter host cells and express foreign proteins without infectious viral progeny, and they are extremely safe immunogens that have already been administered to many people. For gene delivery, the E3 region, described above as a cluster of viral genes potentially controlling pathogenesis, has been physically or functionally deleted. Experience with Ad/SV40, described above, paved the way for these constructs by demonstrating that the Ad E3 region is not essential for viral replication. The E3 region can be

replaced with foreign DNA: insertion of the hepatitis B surface antigen (HBsAg) gene in place of the partially deleted Ad E3 results in the expression of HBsAg which elicited an antibody response in hamsters. Recently, many additional foreign genes have been cloned into Ad vectors. Foreign genes have also been placed and expressed in other Ad sites including positions downstream from the Ad major late promoter (MLP). The Ad MLP is a very active transcriptional start site which results in the expression of large amounts of foreign proteins. To elicit higher titers against a given antigen, duplicate cloning of the gene into several serotypes is performed, permitting booster immunizations without augmentation of a serotype-specific anti-Ad-neutralizing antibody response. Since there has been extensive use of the Ad4 and 7 serotypes in young adults in the military, these types are obvious choices for such recombinant vaccines. The efficacy of Ad constructs designed for immunization is largely dependent upon viral replication and expression of foreign proteins.

Ad constructs designed for gene therapy are replication defective. Foreign genes are inserted into deleted E1A and E1B regions. Growth of these vectors is dependent upon a cell line that is stably transfected with the E1A and E1B sequences. The viruses are infection competent and enter host cells where they efficiently transcribe inserted sequences without the production of significant progeny virus. Human trials have been attempted to test Ad constructs containing the cystic fibrosis gene, one of the numerous inserts placed into Ad vectors to date. Genes that can replace congenitally absent gene products and genes that can control cell growth or promote cell death of malignant cells have been engineered into Ads for therapeutic purposes. The p53 gene and the herpes simplex thymidine kinase gene (used with ganciclovir) are examples of this approach. Adenoviruses that have cell death genes such as Fas are also being used to control the overgrowth of vascular wall myocytes and endothelium after angioplasty. In many of these situations, there is a need for prolonged expression of the transgene or the requirement to re-administer the vector. However, the immune response to the initial injection of Ad, or even preexisting immunity from natural Ad infection, may preclude this possibility. A number of approaches to solve this problem have been undertaken in model systems, including short-term immunosuppression with FK506 or cyclosporine at the time of vector administration; oral or intrathymic tolerance with viral proteins; or using the immunosuppressive properties of overexpressed Ad E3. Inhibition of the antibody response to replication-deficient Ads containing overexpressed E3 genes has

allowed readministration of an Ad vector containing a functional bilirubin conjugating enzyme for correction of an enzymatic defect in rat liver. Though the expression of Ad-inserted genes is prolonged in some tissues, many problems remain to be solved to ensure the success of Ad vectors as delivery systems for gene therapy; achieving long-term expression of foreign Ad-inserted genes in the desired tissue(s) and circumventing host immune responses that ultimately lead to rejection of delivered genes are significant issues that must be resolved. This very active area of research is likely to lead to significant advances in the near future.

Therapy

Ads have remained rather resistant to antiviral chemotherapy. Although Ads code for their own viral DNA polymerase, this enzyme has not been hitherto exploited as a target for chemotherapy. The nucleoside analogs effective in the treatment of herpes simplex virus have not been effective in controlling Ad disease.

ADHESION MOLECULES

Margaret A Adelsman and Yoji Shimizu, Department of Laboratory Medicine and Pathology, Center for Immunology, University of Minnesota Medical School, Minneapolis, Minnesota, USA

In 1922, biologist Warren Lewis wrote, if 'cells (were) to lose their stickiness for one another and for the supporting extracellular white fibers, reticuli, etc., our bodies would at once disintegrate and flow off onto the ground. . . . The so-called cement, so commonly described as existing between various types of cells, may possibly be an adhesive substance'. Over 75 years later, we now know that this necessity for cells to adhere to their surroundings or to their cellular neighbors is reflected in the vast array of molecules identified that mediate cell adhesion. In the immune system, adhesion molecules are essential to many, if not all, aspects of leukocyte function, including normal recirculation of lymphocytes through lymphoid organs, recruitment of leukocytes into inflammatory sites, antigen-specific recognition, and wound healing. Defects in adhesion molecule expression can result in immunodeficiency, and the central role of adhesion molecules in the immune system suggests that adhesion can be used as a therapeutic strategy for intentional modulation of the immune response.

Five main structural families of adhesion molecules have been identified: integrins, immunoglobulin superfamily (IgSF) proteins, selectins, mucins and cadherins (Table 1). This discussion will focus on an introduction to the structure and function of these adhesion molecules, followed by emerging concepts of how the distinct functions of these many

adhesive proteins are integrated to mediate key immunological processes.

Integrins

The integrin family of adhesion molecules is composed of structurally related proteins that combine to form noncovalent $\alpha\beta$ heterodimers. Currently 16 α subunits and eight β subunits have been cloned, resulting in a minimum of 22 different combinations. The VLA (very late antigen) integrins, leukocyte integrins, and cytoadhesins represent integrin subfamilies based on the pairing of α subunits with the β_1 , β_2 or β_3 subunits, respectively. However, the identification of five other β subunits, together with the ability of certain α subunits to associate with more than one β subunit, blurs the distinctions between these integrin subfamilies. Integrin ligands include extracellular matrix (ECM) proteins, as well as cell surface proteins. Many of the integrin cell surface counter-receptors are members of the immunoglobulin (Ig) superfamily (see below). In addition, some bacteria and viruses use integrins to bind to host tissue. Ligand binding specificity is contributed by both α and β subunits. The ligand binding regions of integrins are invariably located at cation-binding sites, and consequently integrin-mediated adhesion is divalent cation dependent.

Table 1 Adhesion molecules in immunology

Receptor	Alternate name	Cell type	Extracellular matrix ligands	Cell surface/ other ligands
1. Integrins				
$\alpha_1\beta_1$	VLA-1	T _a , Mono, NK	COLL, LAM	
$\alpha_2\beta_1$	VLA-2	B, T, PI, Endo	COLL, LAM	Echovirus
$\alpha_3\beta_1$	VLA-3	B	COLL, LAM, FN, Epiligrin, Entactin/Nidogen	Invasin
$\alpha_4\beta_1$	VLA-4; LPAM-2	Thym, Mono, B, T, NK Eosin, Eryth _{imm}	FN, Thrombospondin	VCAM-1, Invasin
$\alpha_5\beta_1$	VLA-5; FnR	Mono, Leuko, T, PI, NK	FN, Thrombospondin	Invasin, L1
$\alpha_6\beta_1$	VLA-6	PI, Mono, T, Thym, NK	LAM	Invasin
$\alpha_4\beta_7$	LPAM-1, $\alpha_4\beta_p$	Some T, NK, Eosin, B	FN	VCAM-1, MAdCAM-1
$\alpha_E\beta_7$	HML-1	Intraepithelial lympho		E-Cadherin
$\alpha_L\beta_2$	LFA-1, CD11a/CD18	Lympho, Neutro, Mono, Macro, NK		ICAM-1, ICAM-2, ICAM-3
$\alpha_M\beta_2$	Mac-1, CD11b/CD18	Mono, Macro, Granulo, NK	FG	ICAM-1, ICAM-2, C3bi, Heparin, <i>B. pertussis</i> hemagglutinin, Haptoglobulin
$\alpha_X\beta_2$	p150/95, CD11c/CD18	Macro, Mono, Granulo, T _a , B _a , NK, Dendr	FG	C3bi, Endothelial ligand?, ICAM-1 (rabbit)
$\alpha_D\beta_2$		Some Macro and CD8 ⁻ T, Large granular lympho		ICAM-3, ICAM-1
$\alpha_V\beta_3$	VN-R	Endo, some B, Macro, Mono, PI	VN, FN, FG, COLL, VWF, Thrombospondin, Osteopontin	CD31, L1
$\alpha_{IIb}\beta_3$	gplIb/IIIa	PI, Megakar	VN, FG, VWF, FN, Thrombospondin	
2. Ig superfamily				
ICAM-1	CD54	Mono, Endo, *(B, T, Thym, Dendr, Endo, Keratino, epithel)		$\alpha_L\beta_2$, $\alpha_M\beta_2$, $\alpha_X\beta_2$, $\alpha_D\beta_2$
ICAM-2	CD102	Endo, Mono, Dendr		$\alpha_L\beta_2$, $\alpha_M\beta_2$
ICAM-3	CD50	Leuko, Dendr		$\alpha_L\beta_2$, $\alpha_D\beta_2$
MAdCAM-1		Peyer's patch HEV, Mesenteric LN HEV, Mucosal lamina propria venules		$\alpha_4\beta_7$, L-selectin
VCAM-1	CD106	Endo _a , tissue Macro, Dendr		$\alpha_4\beta_1$, $\alpha_4\beta_7$
CD31	PECAM-1	PI, Endo, Mono, Granulo, some T		$\alpha_V\beta_3$, CD31
CD2	LFA-2, Leu-5	Thym, T, NK		LFA-3 (CD58), CD48, CD59
3. Selectins				
L-Selectin	CD62L, LECAM1 Leu-8, LAM-1	Most B and T, Granulo, NK Thym _{imm} , some mature Thym, Mono, bone marrow myeloid progen, eryth precursors, Eosin		GlyCAM-1, MAdCAM-1, CD34, Sgp200
E-Selectin	CD62E, ELAM-1, LECAM-2	endo _a		PSGL-1, CLA, ESL-1
P-Selectin	CD62P, GMP-140, PADGEM, LECAM-3	Endo _a , PI, Megakar		PSGL-1

Table 1 Continued

Receptor	Alternate name	Cell type	Extracellular matrix ligands	Cell surface/ other ligands
4. Mucins				
GlyCAM-1		PLN HEV, hemato progen		L-selectin
CD34		Wide intravascular expression		L-selectin
MAdCAM-1		See above (Ig superfamily)		$\alpha_4\beta_7$, L-selectin
5. Cadherins				
E-cadherin	Arc-1, L-CAM, Cell CAM 120/80, uvumorulin	Epithel		E-cadherin, $\alpha_E\beta_7$, internalin
6. Other adhesion molecules				
CD44	Hermes, Pgp-1, H-CAM, ECMR III	Wide expression	COLL, osteopontin	HA
VAP-1		HEV, PLN HEV, Synovium, tonsils		?
LVAP-2	CD73	HUVEC, B, CD8 ⁺ T, Lymphoid and nonlymphoid venules		?
uPAR		Mono, Neutro, T _a , Endo	VN	uPA

Ligands: FN, fibronectin; VN, vitronectin; COLL, collagen; HA, hyaluronic acid; LAM, laminin; FG, fibrinogen; VWF, von Willibrand factor. *Cell types:* Pl, platelet; T_a, activated T cell; Endo, endothelial cell; Mono, monocyte; Thym, thymocyte; PBL, peripheral blood leukocytes; NK, natural killer cells; Eosin, eosinophils; Eryth_{imm}, immature erythroid cells; Leuko, leukocytes; T_m, memory T cells; Epithel, epithelial cells; Lympho, lymphocytes; Neutro, neutrophils; Macro, macrophages; Granulo, granulocytes; Dendr, dendritic cells; Megakar, megakaryocytes; endo_a, activated endothelial cells; HEV, high endothelial venules; LN, lymph nodes; HUVEC, human umbilical vein endothelial cells; *, inducible expression.

The cytoplasmic domains of both the α and β subunits are critical to regulating the ability of integrins to mediate cell adhesion, as well as for transmitting information into the cell interior. Furthermore, recent studies have identified a number of intracellular proteins that associate with or are functionally coupled to integrins via these cytoplasmic tails. Additional complexity in the integrin subfamily is likely, given recent findings that variant forms of the β_1 and β_3 subunits exist that have different cytoplasmic tails as a result of alternative splicing.

Immunoglobulin (Ig) superfamily

Cell surface proteins of the Ig superfamily are characterized by the presence of a variable number of related 70–110 amino acid Ig-like domains originally described in the Ig variable and constant regions. Several IgSF members have been implicated in cell adhesion. CD2 has been shown to bind several distinct ligands, including the IgSF members CD58, CD48 and CD59. CD31, which can mediate homophilic adhesion, has also been implicated in binding to the $\alpha_v\beta_3$ -integrin. The integrin counter-receptors ICAM-1, ICAM-2, ICAM-3, VCAM-1 and MAdCAM-1 (Table 1) round out the list of IgSF adhesion molecules described to date. MAdCAM-1 is a unique IgSF member in that it contains mucin-like properties in addition to Ig domains (see below).

Selectins

Selectins represent a family of three structurally and functionally related adhesion molecules: E-selectin, P-selectin and L-selectin. Each selectin consists of an extracellular lectin-like domain, an EGF-like domain, and variable numbers of a consensus repeat bearing homology to complement proteins, followed by transmembrane and short intracellular sequences. The lectin-like domains are primarily responsible for Ca^{2+} -dependent interactions with fucosylated, mucin-like ligands. Functionally, the rapid association and dissociation rate constants that characterize selectin-mediated adhesion allow selectins to function as important initiators of leukocyte adhesion to endothelium under conditions of shear flow. A role for selectins as signal transducing receptors is also now becoming evident.

Mucins

Mucins are characterized by their extensive and dense array of carbohydrates. The carbohydrate linkages are primarily O-linked with sulfated core groups, termed sialyl Lewis x (sLe^x). The mucins characterized to date are primarily selectin counter-receptors. L-Selectin binds to at least four distinct mucins: GlyCAM-1, MAdCAM-1, CD34, and a poorly characterized protein called Sgp200. As men-

tioned previously, MAdCAM-1 has both Ig domains and a mucin domain, allowing it to bind to both an integrin ($\alpha_4\beta_7$) and a selectin (L-selectin). GlyCAM-1 is somewhat unique in that it lacks a transmembrane domain. PSGL-1 binds both E- and P-selectin, although additional ligands have been described for each of these selectins. The E-selectin ligand ESL-1 appears to require N-linked carbohydrate structures rather than the typical O-linked sialomucin structures. The CLA antigen also binds to E-selectin and is expressed on a subset of memory T cells that preferentially migrate to the skin. The protein backbones of mucins are also postulated to play a role in binding specificity.

Cadherins

Cadherins have been implicated in Ca^{2+} -dependent homotypic aggregation of nonlymphoid cells and play an important structural role in cell-cell junctions. Although there are several different cadherins, to date only E-cadherin has been implicated in regulating immunological function. Intraepithelial lymphocytes express the $\alpha_E\beta_7$ -integrin, which binds to E-cadherin expressed on epithelial cells. This adhesive interaction has been proposed to play a role in retaining $\alpha_E\beta_7$ -expressing T cells at specific tissue sites *in vivo*. E-Cadherin is also the cell surface receptor for the *Listeria monocytogenes* protein internalin.

Other adhesion molecules

Several molecules that are not easily categorized into these adhesion molecule families are listed in Table 1 and deserve mention here. VAP-1 is an adhesion molecule that is expressed on endothelium derived from peripheral lymph nodes, synovium and tonsils, and may play a role in tissue-specific migration of lymphocytes to synovial tissue. LVAP-2 is a putative endothelial adhesion molecule for lymphocytes and has been found on human umbilical vein endothelium (HUVEC), lymphoid and nonlymphoid venules, B cells, and CD8^+ T cells. The urokinase plasminogen activator receptor (uPAR) has been shown to bind vitronectin, as well as regulate the binding activity of β_1 - and β_2 -integrins (see below). CD44 is a widely distributed molecule that is related to cartilage link proteins and proteoglycan core protein. The CD44 transcript can undergo extensive alternative splicing, generating many different protein isoforms. Several CD44 ligands have been reported, the most notable being hyaluronic acid. Antibodies to CD44 can inhibit lymphocyte recirculation, and, like selectins, CD44 binding to hyaluronic acid can support

lymphocyte rolling under shear flow. However, the precise function of CD44 in the immune system remains elusive.

Roles of adhesion molecules in regulating immune function

As mentioned previously, the wide array of adhesion molecules and ligand possibilities provides for exquisite specificity as well as diversity in the tasks adhesion molecules perform in the immune system. Some salient points regarding the importance of these molecules in both normal immune regulation and with respect to the disease state are addressed below.

Adhesion molecules and lymphocyte recognition

The process by which an antigen-specific cytotoxic T lymphocyte (CTL) recognizes and kills a target cell has provided a valuable system for elucidating the function of adhesion molecules in the immune response. In the early 1980s, several monoclonal antibodies were identified that inhibited CTL killing. Subsequent analysis revealed that these antibodies recognize the adhesion molecules LFA-1, a β_2 -integrin, CD2 (LFA-2), and its cellular counter-receptor LFA-3 (CD58). Further analysis of CTL killing identified the first LFA-1 counter-receptor, ICAM-1. Antibodies against these molecules are effective in inhibiting CTL function, because they impair the physical contact between the CTL and the target cell that is required for T cell activation to occur. Thus, one function of adhesion molecules during T cell activation is to provide the adhesive force necessary to allow for effective binding of the antigen-specific T cell receptor with major histocompatibility complex (MHC)-peptide complexes on the antigen-presenting cell. In addition, adhesion molecules also provide intracellular signals during T cell activation that further facilitate T cell activation (see below).

Adhesion molecules and leukocyte recruitment and recirculation

Interaction of circulating blood cells with endothelial cells is essential for the recruitment of lymphocytes to sites of injury and inflammation and for normal recirculation of lymphocytes. The successful movement of leukocytes out of the bloodstream through the endothelium and into the underlying tissue requires the coordinated and sequential interaction of adhesion molecules on the leukocyte and the endothelium, as well as the correct temporal expression of activating signals provided by cytokines and chemokines. This process has been defined

generally as the multistep paradigm of leukocyte adhesion to endothelium. The process of adhesion under shear flow is typically initiated by low-affinity binding of leukocytes to activated endothelium, which results in a characteristic rolling or tumbling of leukocytes along the endothelial surface. Although selectins typically mediate rolling, α_4 -integrins can also mediate rolling in the absence of a contribution from selectins. Upon encounter with an appropriate stimulus, rolling can be converted rapidly into stable, shear-resistant attachment of leukocytes to the endothelial surface. This is accomplished by rapid agonist-induced activation of integrins such as $\alpha_4\beta_1$ (VLA-4), $\alpha_4\beta_7$, LFA-1, and Mac-1. A number of stimuli have been proposed to serve as the 'trigger' that activates integrins in this process, including chemokines immobilized on the endothelial surface by proteoglycans and, perhaps, intracellular signals generated by the selectins during rolling. Following tight adhesion to the endothelium, leukocytes migrate through the endothelium into the underlying tissue. Current evidence suggests a role for chemotactic factors, integrins and CD31 in this process. Thus, the successful extravasation of a leukocyte from the bloodstream into tissue requires the coordinated and sequential interaction of different adhesion molecules, each of which serves to carry out distinct phases of the process. Underlying this orchestrated utilization of adhesion molecules is the role of soluble factors, which serve to dictate the spectrum of adhesion molecules expressed on the endothelial surface, as well as to provide the appropriate signals and chemotactic gradients that initiate key steps in this cascade of adhesive events.

Regulation of adhesion molecule expression and function

The adhesive nature of cells is regulated at many levels. The level of expression of adhesion molecules on the cell surface is dependent in large part on the activation status of the cell. Activation of endothelial cells with inflammatory cytokines, such as interleukin 1 (IL-1) and tumor necrosis factor α (TNF α), results within hours in an increase in expression of E-selectin, ICAM-1 and VCAM-1. This cytokine-induced expression of these adhesion molecules is due to transcriptional upregulation of the genes encoding these molecules. P-selectin is also expressed on activated endothelium, as well as on platelets. However, P-selectin is stored in granules, ready to be upregulated within minutes in response to stimulation. Stimulation of neutrophils with agonists such as formyl-Met-Leu-Phe (fMLP) also results in the rapid upregulation of the Mac-1 integrin due to

fusion of intracellular granules containing Mac-1 molecules with the plasma membrane.

Adhesion molecules can also be rapidly lost from the cell surface. The most notable example is L-selectin, which is constitutively expressed on most peripheral blood leukocytes. However, leukocyte activation can result in rapid proteolytic cleavage (shedding) of L-selectin from the cell surface. Although the protease responsible for L-selectin shedding has not been identified, the cleavage of L-selectin from the cell surface has been demonstrated to be important for leukocyte interactions with endothelium. Other adhesion molecules, including CD44, E-selectin, ICAM-1 and VCAM-1, can also be found in soluble form. The functional significance of soluble adhesion molecules is not entirely clear, but changes in the level of expression of soluble adhesion molecules in various disease states have been noted.

Stable changes in the expression of adhesion molecules can also be observed during the process of lymphocyte differentiation. For example, when naive T cells are activated, some of the activated T cells differentiate into memory T cells. These memory T cells can be distinguished from naive T cells by differential expression of several adhesion molecules. Some adhesion molecules, such as the LFA-1 integrin, β_1 -integrins and CD44, show increased expression on memory T cells, while others, such as L-selectin, show reduced expression. These differences in adhesion molecule expression on naive and memory T cells are believed to be responsible in part for the differences in naive and memory T cell recirculation *in vivo*. For example, uniform expression of L-selectin on naive T cells is believed to be critical for the preferential migration of naive T cells into peripheral lymph nodes via adhesion and transmigration through peripheral lymph node high endothelial venules (HEV). Differentiation of thymocytes is also characterized by discrete changes in the expression of various adhesion molecules.

The functional activity of adhesion molecules can also be regulated by cellular activation. Stimulation of leukocytes and platelets results within seconds to minutes in rapid increases in integrin-mediated adhesion that do not require changes in levels of integrins on the cell surface. Such activation of integrins from a latent cell surface form is an essential element of the multistep paradigm of leukocyte interactions with endothelium. Furthermore, the ability of T cell receptor stimulation to activate integrins in such a manner implicates this mode of regulation in enhancing T cell contact with antigen presenting cells. T Cell receptor stimulation has also been reported to increase the adhesiveness of the CD2 molecule. The intracellular mechanisms by which activation rapidly

upregulates the adhesive nature of these molecules remain poorly defined.

Adhesion molecules may also be regulated by other molecules that physically associate with adhesion receptors and consequently alter adhesive activity. Integrin-mediated cell adhesion to fibronectin has been shown to be inhibited by expression of the uPAR, which physically associates with β_1 -integrins as well as the Mac-1 integrin. Studies of four transmembrane-containing (TM-4) proteins (CD9, CD63 and CD81/TAPA-1) have also demonstrated an association of these proteins on the cell surface with integrins, although the functional significance of this association for integrin function remains unclear. These observations suggest that additional membrane localized proteins may be identified in the future with similar roles of enhancing or inhibiting adhesion molecule function through physical association in the plasma membrane.

Signal transduction through adhesion molecules

While the term 'adhesion molecules' highlights the ability of these receptors to serve as the 'glue' that binds cells to each other and to ECM, it is now clear that engagement of adhesion molecules also results in the generation of intracellular signals that alter cell function. Evidence for adhesion molecule-mediated signal transduction is now plentiful. Analysis of integrin-mediated signaling, in particular, has been extensive and highlights the broad array of intracellular signals that adhesion molecules can transduce when appropriately stimulated. In the immune system, initial evidence for integrin-mediated signaling has been obtained by findings that interactions between integrin counter-receptors and ECM ligands can enhance T cell receptor-mediated activation of T cells. More direct evidence for integrin-mediated signaling has developed from biochemical studies of various signal transduction pathways using a large number of cell types. Integrin engagement by ligand or monoclonal antibodies has been shown to result in the activation of early signaling events, such as calcium influx, a rise in intracellular pH, and the activation of a number of intracellular kinases. These include tyrosine kinases, mitogen-activated protein kinases (MAPKs) and lipid kinases. Integrin stimulation also results in the tyrosine phosphorylation of a number of proteins, most notably an intracellular tyrosine kinase, focal adhesion kinase (pp125^{FAK}), the p130^{Cas} adapter protein, and several cytoskeletal proteins. In adherent cells, such as fibroblasts, many of these tyrosine phosphorylated proteins are associated functionally with integrins at focal adhesions,

the point of cell contact with the underlying ECM. A link between integrin-mediated tyrosine phosphorylation of pp125^{FAK} and activation of the Ras signaling pathway has been suggested. Certain transcriptional effects of integrin activation have been noted, including the induced expression of metalloproteinase and transcription factor genes. A critical role for integrins in cell survival has also been documented. However, the functional relationship between early integrin-mediated activation events, such as tyrosine phosphorylation, and later events, such as induction of gene transcription, remains poorly characterized.

Integrins are not the only adhesion molecules that transduce signals upon engagement. Stimulation of certain selectins (L- and E-selectin) and IgSF members (CD2, CD31) can upregulate β_1 - and β_2 -integrin activity. Thus, signals generated by one type of adhesion molecule can alter the functional activity of another. In the case of CD2, a role for CD2 as a signaling molecule was appreciated before any role for the molecule in adhesion was uncovered. Although not as extensively studied, it is now becoming clear that selectins, like integrins, also initiate intracellular signals upon ligand engagement. While typical markers of intracellular cascades, such as Ca²⁺ influx and tyrosine phosphorylation, have been noted following activation of many of these adhesion molecules, notable distinctions also appear to be emerging. Thus, there is likely to be considerable complexity and specificity in adhesion molecule signaling, reflecting the complex but specific nature of receptor-ligand interactions discussed previously and shown in Table 1.

Adhesion molecules and disease

The physiological relevance of adhesion molecule function is elegantly demonstrated by naturally occurring defects in the expression and/or function of adhesion molecules, which consequently leads to disease. The inherited bleeding disorder, Glanzmann's thrombasthenia, is caused by loss of expression and/or function of the $\alpha_{IIb}\beta_3$ -integrin on platelets. Consequently, platelet aggregation, which is necessary to prevent excessive loss of blood during injury, fails to occur. The importance of adhesive functions of the β_2 -integrins has been demonstrated by a syndrome termed leukocyte adhesion deficiency (LAD-1). Patients afflicted with this disease lack expression of the β_2 -integrin subunit, and the adherent function of their macrophages and granulocytes is essentially absent. As a result, affected individuals have severely reduced life expectancies and suffer from recurrent bacterial and fungal infections.

Recently, a syndrome, termed LAD-2, with a similar phenotype to that of LAD-1 has been characterized. LAD-2 results from a defect in fucose metabolism, which impairs the expression of the carbohydrate ligands recognized by selectins. The neutrophils of afflicted individuals fail to bind endothelial cells, further demonstrating the importance of adhesion molecules in normal physiological cell functions.

The *in vivo* relevance of adhesion molecules in the immune response has also been demonstrated experimentally in a variety of ways. Altered expression and/or function of adhesion molecules has been noted in various disease states. The functional relevance of these findings has been demonstrated by *in vivo* blocking studies using antibodies specific for adhesion molecules, soluble adhesion receptors, blocking peptides or carbohydrates, and antisense oligonucleotides. Thus, targeting of adhesion molecules with these reagents has been shown to be effective in many different animal models of human disease, including models of ischemia/reperfusion injury, acute inflammation, allograft rejection during organ transplantation and various chronic inflammatory disorders such as rheumatoid arthritis. In most of these studies, the primary focus has been on blocking or modulating leukocyte or lymphocyte attachment to endothelial cells. Modulation of adhesion molecule expression has also been shown to be effective in inhibiting tumor cell growth and metastasis.

The use of homologous recombination in embryonic stem cells to generate mice deficient in expression of various adhesion molecules has also been utilized to uncover the function of these molecules *in vivo*. Mice lacking expression of several individual integrin α and β subunits have been produced. For the most part, these integrin mutations have been either embryonic or neonatal lethal in phenotype, emphasizing the global importance of integrins in embryonic development. Mice lacking expression of signaling components linked to integrins, such as pp125^{FAK}, also fail to develop normally. Mice lacking expression of the β_7 -integrin subunit are viable, but exhibit defects in development of gut-associated lymphoid tissue, presumably due to the inability of T cells to migrate into this tissue site. L-selectin, E-selectin and P-selectin knockout mice have also been individually generated, confirming the importance of these molecules in leukocyte-endothelial interactions. E-selectin-deficient mice present with little change in phenotype from wild-type. However, mice genetically deficient for both E- and P-selectin show a synergistic reduction in neutrophil and lymphocyte adhesion to endothelium, confirming roles for both P- and E-selectin in this process.

Conclusions

Clearly, the variety of adhesion molecules described to date lends itself well to diverse mechanisms of immune regulation. New adhesion molecules are likely to be discovered, and the mechanisms of adhesion molecule function will continue to be further delineated. Given the breadth of this diversity, it will be crucial to begin a closer scrutiny of the structural and signaling requirements of these molecules. A more precise knowledge of these roles may lead to valuable tools that target adhesion molecules for therapeutic intervention in diseases whose etiology includes aberrations of the immune response.

ADJUVANT ARTHRITIS

Irun R Cohen, Department of Immunology, The Weizmann Institute of Science, Rehovot, Israel

Adjuvant arthritis (AA) is a disease induced in rats by immunization with killed *Mycobacterium tuberculosis* (MT) organisms in oil, a substance known as complete Freund's adjuvant. The work of C.M. Pearson and his colleagues in the 1950s and 1960s helped establish AA as a standard model of chronic inflammation produced by immunological processes. Two opposing theories were put forth to explain the pathogenesis of AA: the first proposed that the joints were damaged as bystanders to an immune response directed to MT antigens disseminated to the sites of inflammation; the second proposed that AA was caused by an autoimmune attack against a cross-reactive self antigen. Despite the uncertainty of its pathogenesis, AA has served for many years as a reliable and convenient model for testing treatments for inflammation.

Induction of AA

AA appears about 2 weeks after immunization of rats to MT. The severity, duration and consequences of the arthritis seem to be influenced by various factors:

1. Genes; major histocompatibility complex (MHC) and other genes contribute to susceptibility. AA is most readily induced in rats and has been studied almost exclusively in this species. Mice, however, were reported to develop AA 2 months after administration of MT.
2. Gender; male rats are more susceptible than are female rats.
3. Microbial environment; germ-free rats and rats

maintained in very clean surroundings are much more susceptible to severe AA than are rats raised in contaminated quarters.

4. Amount of MT; the maximum clinical score of the arthritis is directly related to the amount of MT administered to the rats. About 0.2 mg of MT produces mild AA. Increasing the dose of MT causes more severe arthritis; a maximum clinical score is usually elicited by 1 mg of MT.
5. State of MT inoculum; finely pulverized MT is much more arthritogenic than is whole MT. Merely mixing the MT in oil is more arthritogenic than is emulsifying the MT in oil.
6. Site of immunization; intradermal inoculation is most arthritogenic, intramuscular is least and intraperitoneal is intermediate.

The severity of acute AA in rats peaks about 2 weeks after the disease first appears. The arthritis then slowly regresses and may disappear totally (for example in dirty female rats); but it may also persist for a year or more (for example in clean male rats). Protracted AA can lead to irreversible damage (ankylosis) to the joints of the extremities.

The rats that recover from AA acquire resistance to further attempts to induce AA. Resistance to AA can also be obtained by first administering MT under conditions that are not arthritogenic; for example, MT administered intramuscularly or without oil. Thus, the clinical expression of arthritis appears to result from many seemingly trivial factors impinging on the process of immunization to MT; the particulars of the immunization determine the nature of the response, which in turn determines the patho-

genic consequences. Such complexity implies regulation.

The hsp65 connection

In 1984 it became possible to study the complexities of AA using an etiologic agent of disease, a clone of T cells capable of adoptively transferring AA, called A2b. It was demonstrated that A2b recognized an MT antigen and an antigen in the proteoglycan moiety of joint cartilage. This supported the autoimmune theory: AA was caused by antigen mimicry between MT and a joint antigen.

The MT epitope recognized by clone A2b was later identified as the nine amino acids at positions 180–188 in the sequence of the 65 kDa heat shock protein (hsp65) molecule of MT. This molecule belongs to the hsp60 family and is closely homologous to the mammalian hsp60 molecules. The general importance of hsp65 to arthritis was suggested by the observation that T cells responsive to hsp65 could be detected in the synovial fluids of patients suffering from rheumatoid arthritis. Moreover, some patients with juvenile arthritis showed immunity to the human hsp60 molecule. Thus, immunity to hsp65/hsp60 could be associated with spontaneous forms of immunological arthritis in humans as well as with AA of rats.

Is T cell immunity to hsp65 the cause or only the result of AA? The answer awaits the resolution of four issues.

1. *Identity of the joint antigen.* The 180–188 peptide recognized by clone A2b is in a variable region of the hsp65 molecule of MT; despite an overall homology of 50%, the 180–186 amino acid sequence is not present in the known mammalian hsp60 molecules. Thus the epitope recognized by A2b in the joints is probably not on the endogenous hsp60 molecule but is likely to be present on another molecule. A very weak homology between the 180–188 peptide and a sequence in the link protein of cartilage proteoglycan exists. This is compatible with the earlier observation that clone A2b recognizes an element in cartilage proteoglycan. However, clone A2b does not proliferate in response to the link protein peptide, so some other cross-reactivity is probably responsible for AA. Cross-reactivity has been sought between hsp65 and chondrocyte and proteoglycan antigens, and between hsp65 and lactoferrin, but these studies have failed to shed any light on pathogenesis. AA seems to be distinct immunologically from the arthritis inducible by immunization to collagen type II, yet spleen cells from rats immunized to
2. *Induction of AA.* The fact that clone A2b caused arthritis led to the hypothesis that the target epitope of AA must be present in the hsp65 molecule of MT. This idea would be more tenable if active immunization to hsp65 were to actually induce AA. However, immunization with hsp65 has as yet failed to induce arthritis. Nevertheless, hsp65 must be involved in the process responsible for arthritis because administration of whole hsp65 or the 180–188 nonapeptide to rats induces resistance to AA.
3. *Specificity of hsp65 immunity.* The immune response to hsp65 is not exclusive to arthritis. It appears that inflammatory exudates outside of the joints, pleural effusions for example, are also rich in T cells responsive to hsp65. Moreover, immunization of some strains of mice with hsp65 or hsp60 has been found to induce diabetes mellitus. The epitope of hsp60 associated with diabetes differs from the 180–188 epitope associated with arthritis. Nevertheless, it is clear that hsp65 immunity is not limited to the inflammation of immunological arthritis. In fact, immunity to hsp65 is not necessarily associated with immunopathology; the T cells of healthy humans respond very well to hsp65 and even to self hsp 60. Moreover, hsp65 is a dominant antigen in the immune response to infection or vaccination with *Mycobacteria* or other bacteria.
4. *Regulation of AA.* AA is a manifestation of the inflammatory reaction, so it is not surprising that AA can be suppressed by various anti-inflammatory treatments, particularly treatments that inhibit proinflammatory cytokines, such as tumor necrosis factor α (TNF α), or that block the T-cell receptor. Interestingly, AA can be inhibited by T cells that recognize specific epitopes from the T-cell receptor of an anti-hsp65 T cell. In addition to regulatory T cells, it appears that antibodies may be important in the regulation of AA. AA can be inhibited by normal immunoglobulin (IVIg) and by immunoglobulins from strains of rats resistant to AA. Furthermore, AA is marked by changes in the glyco-

collagen type II could partially inhibit AA. Thus, the immunological connection between MT and AA, and between hsp65 and the joints, remains circumstantial.

sylation of antibodies of the IgG1 and IgG2b isotypes.

The future

Although AA has been a familiar laboratory model for decades, we are only now appreciating the charm of its complexity and the value of the secrets it can reveal about health, autoimmunity and the immunology of the host-parasite interaction. As we might have guessed from the constellation of elements affecting its induction, the development of AA is an outward expression of the subtleties of immune regulation. Health or disease is not the mere outcome of response or nonresponse. The immune system can respond to MT and to the hsp65/hsp60 molecules in many ways and it is the nature of this response that determines health or disease. 'The nature of this response' is a conceptual handle of the black box of immunological regulation. Present research is attempting to open the box to reveal the clockwork of the system.

The word 'adjuvant' is used in many ways in biology and medicine. Most commonly, it is used to refer to compounds that act in a nonspecific manner to augment specific immunity to an antigen. A series of experiments in 1925 by Ramon first indicated that compounds of a vaccine formulation other than antigen itself are important for a successful biological response. Ramon found that the addition of substances as diverse as metal salts, oil, tapioca and pyogenic bacteria to his vaccine preparations increased the antitoxic response to diphtheria and tetanus toxins. These simple but elegant experiments started a search, which is still ongoing, for vaccine adjuvants that are suitable for a wide range of uses.

Older vaccines contained antigen preparations that were frequently impure and poorly characterized. Retained contaminants resulted in toxicity and antigenic competition. In some cases, such as with killed bacterial vaccines, the contaminants themselves were adjuvants. Technical advances in biochemistry and molecular biology have led to the production of increasingly pure antigens in order to induce a specific immune response. Modern antigen preparations are usually very well characterized and are now often synthetic or recombinant constructs. These new preparations have reduced side-effects but in many cases are less immunogenic than older killed or subunit vaccines; therefore, in most cases, adjuvants are needed to increase their potency. Adjuvants are substances capable of stimulating an earlier, stronger or more prolonged response to an antigen. In some systems the antibody or the cell-mediated (CMI) immune response, as well as the antibody class or subclass and/or T helper subset (T_H1 and T_H2), can be selected for by manipulating the adjuvant and vaccine formulations.

There are several properties that an adjuvant should ideally possess to be effective, safe and practical for use in human vaccines. Foremost, it should accomplish its desired goal without toxicity. Additionally, however, it should be well characterized and stable even in the absence of refrigeration. Although there are numerous compounds presently utilized as adjuvants in animals, no compound fits all of these desired criteria for clinical use.

The development of vaccine adjuvants has been largely empirical. Antigen preparations have tra-

ditionally been administered with and without an adjuvant and the specific immune responses directed towards the antigen have been compared by assessing antibody and/or CMI utilizing assays current for the epoch of the experiment. Improved immunologic and biochemical techniques are permitting the construction of new, better characterized adjuvants and vaccine formulations. Nonetheless, a fundamental understanding of the mechanisms by which adjuvants stimulate immune responses is incomplete, slowing progress in the field and making classification of the numerous and diverse adjuvants that are currently known somewhat arbitrary.

Compounds with adjuvant activity (Table 1)

Aluminum compounds

Aluminum was used as an adjuvant as early as 1926 by Glenny. The positive results of these studies led to its use worldwide in animal and human vaccines in the following decades. Aluminum continues to be

utilized today, primarily because it is generally regarded as safe.

Vaccines are prepared by adsorbing the antigen on to aluminum compounds such as aluminum hydroxide or phosphate, or by precipitating the antigen with alum $[\text{Al}(\text{SO}_4)_2 \cdot 12 \text{H}_2\text{O}]$. Several hypotheses have been proposed for its mechanism of action. However, most investigators believe that the primary mechanism by which aluminum acts is by the creation of a depot so that the antigen is relatively slowly released, prolonging the time in which it can interact with antigen-presenting cells and lymphocytes. Despite its wide acceptance for clinical use, there are some disadvantages in the use of aluminum as an adjuvant for human vaccines. Although clinical trials have confirmed that aluminum is safe, it augments antibody responses much more effectively than CMI. Furthermore, its adjuvanticity varies depending upon the antigen. Other problems are that vaccines containing aluminum cannot be frozen for storage or lyophilized, and therefore require refrigerated transport. Overall, aluminum compounds are adequate adjuvants if antibody is sufficient for protection and the antigen is a strong immunogen.

Hydrophobic compounds and surfactants

The empirical knowledge that hydrophobic substances tend to augment antibody production and CMI has been a framework for the development of several classes of adjuvants. Examples include emulsions containing water and oil, lipopolysaccharide (LPS), liposomes and saponin.

The use of emulsions began in the 1930s with the experiments of Freund, who mixed paraffin oil with solutions of killed mycobacteria. This compound, called Freund's complete adjuvant, is one of the most potent adjuvants known. It is, however, too toxic for use in humans. An oil emulsion without the mycobacteria, called Freund's incomplete adjuvant, is less toxic and was clinically utilized in the past for influenza and poliomyelitis vaccines. It is no longer used because of a low incidence of induced sterile abscesses, the question of carcinogenicity in mice, lot-to-lot variation, lack of long-term stability, and the fact that CMI is not substantially boosted.

The use of liposomes as adjuvants has been studied experimentally for 20 years. Adjuvant activity depends upon the charge, the number of multilamellar phospholipid layers, the composition and the method of preparation. Both antibody and CMI are augmented. Some liposome preparations induce a potent cytotoxic T lymphocyte (CTL) response. A physical association between antigen and liposome is necessary, suggesting that a depot effect and/or altered antigen presentation are important mechanisms.

Stability, long-term toxicity and lot-to-lot variation are potential problems.

Saponin is a compound that was initially purified from the bark of the tree, *Quillaja saponaria*. It has been studied for decades, but is too toxic for use in humans. Chemical extraction procedures led to the less toxic derivative, Quil A, which is utilized widely for veterinary vaccines, and subsequently to QS21. Complexes of cholesterol, Quil A and amphipathic antigen (called ISCOMs) provide an efficient means of inducing a potent antibody and CMI response, and may provide a formulation in which the toxicity of Quil A is diminished, while its efficacy, including its ability to induce CTL, is maintained. QS21 is less toxic than both parent compounds, and can stimulate a $\text{T}_\text{H}1$ response and antigen-specific CTL in addition to antibody responses. Its safety and efficacy are being evaluated in several clinical trials.

Adjuvants of bacterial origin

It is not surprising that animals have evolved an elegant immune response to bacterial products. Although many adjuvants of bacterial origin are too toxic in their natural form for use in humans, analogs of LPS and muramyl dipeptide have been developed for reduced toxicity.

Experiments in the 1960s and 1970s revealed that the adjuvant active moiety of LPS is a unique bacterial lipid called lipid A. Chemical manipulations such as phthalylation or succinylation of the LPS or removal of a phosphate group from lipid A to create monophosphoryl lipid A results in diminished toxicity of the compound, while retaining adjuvanticity.

Freund's complete adjuvant consists of an oil emulsion containing killed mycobacteria. Successive biochemical studies revealed that one of the most active components is *N*-acetylmuramyl-L-alanyl-D-isoglutamine (muramyl dipeptide, MDP). Over the last decade, numerous analogs of MDP have been synthesized and studied. Hydrophilic MDP analogs administered in saline induce mainly antibody responses, whereas CMI is induced if MDP is given together with antigen in oil emulsions or in liposomes. Similarly, if the MDP analog itself is made lipophilic by the addition of glycerol mycolate, CMI is induced. Nontoxic candidate MDP analogs for clinical use are murametide (NAcMur-L-Ala-D-Gln-OCH₃), murabutide (NAcMur-L-Ala-D-Gln- α -*n*-butyl ester) and muramyl tripeptide (MTP-PE). A combination of threonyl-MDP with a squalane and pluronic copolymer emulsion (Syntex adjuvant formulation, SAF) is a potent adjuvant in experimental models. MTP-PE and SAF are currently being

assessed as adjuvants for some human immunodeficiency virus (HIV) vaccine candidates.

The mucosal immune response is important for protection against many infections. Cholera toxin and *Escherichia coli* heat-labile enterotoxin (LT) are the most potent adjuvants described for the induction of mucosal immunity. Unfortunately, neither can be used in humans because of associated toxicity. Recently, however, a nontoxic derivative of LT has been developed which retains its adjuvanticity for mucosal immunization.

Cytokines

Interleukin 1 (IL-1), IL-2, IL-4, IL-6 and interferon γ (IFN γ) stimulate immune responses when injected together with antigens. A synthetic nonapeptide of IL-1 β has been identified that possesses immunostimulatory but not inflammatory activity. Other cytokines are attractive candidates for the development of vaccines that specifically stimulate certain arms of the immune system. For example, IL-12 is a potent stimulator of T_H1 responses and therefore may be helpful as a component of vaccines for some parasitic diseases, such as leishmaniasis, or for viral infections for which these T cell responses play an essential role.

Adjuvant and antigen combinations

Several strategies have been utilized to increase the immunogenicity of small or weak antigens. To increase its apparent molecular weight, an antigen can be coupled on to an inert support, coupled chemically or genetically to a larger 'carrier' molecule (such as tetanus toxoid), or coupled to itself or other antigens to create a univalent or polyvalent polymer. Peptides can be also directly synthesized on to a branching core structure to create defined branching molecules with multiple antigenic peptides (called MAPs). Polysaccharides that are T cell independent can be coupled to protein carriers to create protein-polysaccharide conjugates that confer T cell-dependent characteristics to the polysaccharide. Similarly, conjugation of the antigen directly to the adjuvant can increase its immunogenicity. Another approach to further augment the immune response is to utilize combinations of adjuvants, such as the use of LPS, MDP, saponin, or cytokines in liposomes or oil emulsions together with the antigen. Biodegradable delivery systems have also been developed that can be utilized for the controlled release of antigen and to target antigen to antigen-presenting cells. In particular, microspheres based on poly(lactic acid) and poly(lactic/glycolic acid) are being actively developed.

Living organisms as vector/adjuvants

An exciting recent approach is to engineer genetically a nonpathogenic but infectious living organism to deliver foreign protective antigen(s) to the immune system. The vaccine recipient is infected with the organism, which is utilized as a vector in order to induce an immune response to the antigen. The first live vector to be utilized was vaccinia virus; however, many other viral or bacterial vectors are now being developed to deliver protective antigens to the immune system. One excellent candidate for the construction of such an attenuated vaccine is BCG, which has already been extensively utilized worldwide in humans as a vaccine that has a very low incidence of serious side-effects. Attenuated *Salmonella* or *Shigella* strains that stimulate local immune responses after oral immunization are also being developed. Viruses, including adenovirus or poliovirus, have considerable potential for the ability to deliver foreign antigens to the immune system. Recombinant poxvirus vectors that are unable to replicate in mammalian species, such as fowlpoxvirus or canarypox, have also been used to elicit antibody and CTL responses against diverse pathogens in animals. A canarypox coding for the HIV-1 envelope proved to be safe and immunogenic in humans. Such live recombinant vaccines may be easier to prepare and administer than existing vaccines. Disadvantages include the risks inherent with all live vaccines and the fact that repeated use of the same vector for different antigens may decrease its efficacy.

Future prospects

Despite the large number of currently known substances that are capable of increasing specific immunity, only aluminum hydroxide is currently utilized routinely as an adjuvant in humans. The major obstacle to the use of the remaining agents is that the toxic:therapeutic ratio is too narrow. The documented dissociation of efficacy from severe toxicity with many adjuvants suggests that acceptable compounds can be developed in the future. With the growing use of sophisticated small antigenic fragments containing defined B and T cell epitopes, such adjuvants will become increasingly necessary. Since different subsets of the immune system may be needed in different settings, it is to be anticipated that multiple distinct adjuvants and vaccine preparations will be desirable. It is therefore appropriate that the adjuvants currently being utilized or studied are highly diverse, including minerals such as aluminum, bacterial products such as LPS and MDP, and living viral and bacterial vectors. Nevertheless, although progress is being made through

modifications of known adjuvants, a fundamental unifying hypothesis as to the necessary mechanisms needed for adjuvanticity is still lacking. As our understanding of the underlying physiology of the immune system broadens, the parameters that are important for the development of newer generations of adjuvants will hopefully become more evident.

ADRENAL AUTOIMMUNITY

Pierluigi E Bigazzi, Department of Pathology, University of Connecticut Health Center, Farmington, Connecticut, USA

Adrenal autoimmunity is currently the most common cause of Addison's disease, a chronic disorder of the adrenal cortex characterized by atrophy of the adrenals. This results in deficient production of adrenocortical hormones together with increased secretion of anterior pituitary adrenocorticotrophic hormone (ACTH). The clinical picture of Addison's disease may comprise weakness, anorexia, nausea, vomiting and weight loss. Hypotension and mucocutaneous hyperpigmentation are usually present. Levels of serum potassium and urea nitrogen are elevated, whereas serum sodium may be decreased. Significant laboratory findings are low plasma levels of cortisol and elevations of ACTH. Stimulation with synthetic ACTH does not result in cortisol increases.

Idiopathic adrenal atrophy is probably an autoimmune disease, as suggested by the facts that the histopathology of the affected adrenals resembles that observed in tissues which are targets of other organ-specific autoimmune diseases, and that autoimmune responses to various adrenocortical antigens have been detected in patients with idiopathic Addison's disease.

Addison's disease can occur as an isolated (sporadic) disorder or in association with other conditions (autoimmune polyendocrinopathy syndrome type 1 or type 2) (see Table 1). Sporadic autoimmune

Addison's disease usually affects young females, who may outnumber male patients by a factor of 4. Contrary to the reported increased incidence of insulin-dependent diabetes mellitus (IDDM) and Hashimoto's thyroiditis, Addison's disease continues to be an extremely rare occurrence. In the United States, its incidence approximates 1 per 4500–6250 patients hospitalized for various disorders. In the London area the prevalence of Addison's disease has been estimated at 30 per million inhabitants and in Denmark it was reported to be 60 per million. In New Zealand there are approximately 4.5 new cases per million population per year.

Pathology and immunopathology

At autopsy, the adrenal glands of most patients with idiopathic Addison's disease are small, very thin and often are very difficult to recognize or may be missing altogether (substituted by adipose and fibrotic tissue). The most characteristic findings by light microscopy are: loss of adrenocortical cells, localized hypertrophy and hyperplasia of adrenocortical cells as well as chronic inflammatory infiltrates (Figure 1). A severe loss of adrenocortical cells is the most characteristic feature of adrenals from patients with autoimmune Addison's disease. Where cortical epi-

Table 1 Human diseases with adrenal autoimmunity

Characteristics	Adult Addisons disease	Autoimmune polyendocrinopathy type 1	Autoimmune polyendocrinopathy type 2
Clinical features	Idiopathic adrenal insufficiency	Idiopathic adrenal insufficiency + hypoparathyroidism + chronic mucocutaneous candidiasis + gonadal failure	Idiopathic adrenal insufficiency + insulin-dependent diabetes mellitus + autoimmune thyroiditis
Age of onset	All ages, but more commonly in adults	Most commonly in childhood	All ages, but more commonly in adults
Gender	Mostly females	Males and females	Mostly females
Prevalence	3–6 per 100 000	Unknown (very rare)	Possibly 50% of adult Addisons patients

thelium is present, it is not arranged in three different zones, but in strands or rows of irregular size, contour and direction. There is loss of cellular outline, swelling and vacuolar appearance. Some cells are extremely large, with granular or vacuolated cytoplasm, others are small. In addition, both hyperplasia and hypertrophy can be observed in adrenals from patients with idiopathic Addisons disease. Scattered islands of cells may be seen in the cortex as well as large well-circumscribed adenoma-like nodules, without typical zonal division of the parenchyma. These cells resemble those of the zona fasciculata, less often those of the zona glomerulosa. They may have a bizarre appearance and sometimes are huge, with deeply pigmented cytoplasm and large hyperchromatic nuclei. A chronic inflammatory infiltrate is usually present, with a prevalence of small lymphocytes. Plasma cells and macrophages are also present, but in lesser numbers. The adrenal medulla is usually intact or infiltrated by a few lymphoid cells. The lymphocytic infiltrate is usually diffuse, but in some areas lymphocytes may form aggregates of various dimensions. Germinal centers are seldom present.

Studies of adrenal immunopathology in patients with Addisons disease have been rather scarce. Direct immunofluorescence of the adrenals has shown dense deposits of immunoglobulin G (IgG) in some areas of the adrenal cortex, with specific fluorescence localized more intensely at the level of the cell membranes. To date, there are no reports on the composition of the adrenocortical lymphocytic infiltrates. However, immunohistopathology studies of micronodules of Cushing's disease have shown that the lymphocytic infiltrates, present around vessel

walls but also inside the nodules themselves, were composed mostly of T cells, usually CD4⁺ with a minority of CD8⁺. In addition, B cells were also present in the infiltrates. It is possible that a similar situation also occurs in the adrenals of patients with autoimmune Addison's disease. Class II major histocompatibility complex (MHC) expression by human adrenal cortical cells appears to be a physiological phenomenon. Approximately 10% of normal adrenocortical cells express MHC class II antigenic determinants. These antigens are mostly localized in the zona reticularis and occasionally may extend to the zona glomerulosa or fasciculata. In adrenal glands from Addison's disease patients, the majority of residual cortical cells show MHC class II antigens, with variation in extent from 50 to 100%. Staining is most intense at the periphery of residual nodules. Adrenal glands from patients with tuberculous Addison's disease have a similar pattern to normal glands, but show class II positivity in cortical cells immediately adjacent to foci of caseous necrosis.

Humoral and cellular autoimmune responses

Newly diagnosed patients with Addison's disease have a variety of circulating autoantibodies to adrenal antigens. Autoantibodies directed against organ-specific antigens localized in the cytoplasm of the adrenocortical cells are present in the circulation of approximately 70% of Addison's disease patients. These antibodies can be detected by indirect immunofluorescence, radioimmunoassay and ELISA, are usually of low titer, belong to the IgG class and react with one or more organ-specific antigens localized in the adrenal cortex. In most cases, immunofluorescence shows that all three layers of the cortex react with adrenal autoantibodies (Figure 2). However, different patterns of staining can be observed: sera from some patients stain all three zones of the cortex, whereas others react with the zona fasciculata and zona reticularis alone. A few sera react with the zona glomerulosa alone. The clinical significance of these findings is unknown, but suggests an immunologic heterogeneity of Addison's disease, with preferential involvement of different adrenal antigens. Complement fixing adrenal autoantibodies have also been observed by immunofluorescence. Autoantibodies to organ-specific surface antigens of adrenal cells are present in the sera of 86% of patients with Addison's disease who have circulating antibodies to adrenal cytoplasmic autoantigens. The adrenal-specific surface antigens appear by immunofluorescence as a continuous rim, but separate granules are visible on focusing over the plasma

Figure 2 (A) Antibodies to adrenocortical antigens (indirect immunofluorescence with serum from a patient with Addison's disease on cryostat section of monkey adrenal). (B) Higher magnification of similar field. (With permission from American Society of Clinical Pathologists, Chicago, USA.)

membrane. Antibodies to steroid-producing cells of other tissues have also been detected in the circulation of patients with Addison's disease. These autoantibodies react with theca interna cells, interstitial cells and corpus luteum cells of the ovary as well as interstitial cells of the testis and placental trophoblasts.

Recent studies using molecular cloning and western blotting have shown that different steroidogenic enzymes of the cytochrome P450 family may be the target autoantigens of autoimmune Addison's disease. Purification of native human adrenal proteins, comparative western blotting using patients' sera and rabbit antibodies against recombinant 21-hydroxylase as well as antibody absorption studies, have demonstrated that steroid 21-hydroxylase P450, an enzyme involved in both the glucocorticoid-synthesizing pathway and the mineralocorticoid pathway, is the major target of adrenal autoantibodies found in patients with isolated Addison's dis-

ease or polyendocrine autoimmune syndrome type 2 (Table 1). On the other hand, patients with polyendocrine autoimmune syndrome type 1 (characterized by adrenal insufficiency, hypoparathyroidism and hypogonadism) have antibodies that react with P450 SCC (cholesterol side-chain cleavage) or, as reported by other authors, another enzyme, the microsomal steroid 17 α -hydroxylase (Table 1). It is still uncertain whether these autoantigens are expressed on the surface of adrenal cells or are otherwise accessible to adrenal antibodies *in vivo*. Finally, IgG preparations from patients with Addisons disease have been reported to cause a dose-dependent decrease of *in vitro* cortisol production and/or DNA synthesis induced by ACTH in guinea pig adrenal segments maintained in organ culture. The blocking effects occurred irrespective of the presence or absence of adrenal cytoplasmic autoantibodies and were attributed to the production of antibodies against the receptor for ACTH. This hypothesis has not been confirmed by recent studies that suggest an inhibitory effect of non-IgG components.

Studies of cellular immunity to adrenal antigens have been based on classical (but now rather outdated) methods to detect delayed hypersensitivity reactions and lymphokine production. In these procedures, peripheral blood lymphocytes from patients were incubated *in vitro* with the putative antigens, often used as a rather crude suspension. Thus, it has been shown that most patients with Addisons disease have cell-mediated immune reactions to adrenal antigens as determined by the leukocyte migration test. There was no correlation with onset of disease, its duration and the presence of adrenal antibodies. The antigen preparations that have been utilized in leukocyte migration studies were organ-specific, but not species-specific, since monkey and porcine adrenals were used with the same success as human adrenals. In some studies the antigenic activity was localized in the mitochondrial but not the microsomal fraction, whereas in other experiments leukocyte migration inhibition was observed after incubation with both components. More modern investigations of cellular immunity (e.g. with steroid 21-hydroxylase P450) are still lacking.

Immunogenetics and disease association

Adrenal autoimmunity may be a heterogeneous condition, as suggested by reports that Addisons disease is inherited in at least three different fashions: autosomal recessive, autosomal dominant with decreased penetrance and X-linked recessive. Inherited susceptibility to autoimmune Addisons disease is linked to

HLA-DR3 and/or DR4, except when the disease occurs as part of type 1 autoimmune polyglandular syndrome. A high prevalence of other autoimmune diseases (ovarian failure, Graves disease, Hashimoto's disease, hypothyroidism and insulin-dependent diabetes mellitus) is associated with Addisons disease (see Table 1).

Animal models of Addisons disease

Idiopathic Addisons disease occurs spontaneously in dogs and more rarely in cats. In the few cases that have undergone autopsy, atrophy, regeneration of adrenocortical cells and chronic inflammation of the adrenal cortex have been observed. The cause of adrenal insufficiency in dogs is probably of autoimmune, not tubercular, origin. A preferential occurrence in Chow-Chow dogs suggests a genetic predisposition. Adrenal autoimmunity with lesions of the chronic inflammatory type has been experimentally induced by immunization of monkeys, rabbits, guinea pigs, rats and mice with suspensions of adrenal cortex in complete Freund's adjuvant. Circulating autoantibodies to the adrenal cortex have been demonstrated in these models, whereas there is a paucity of reports on cellular autoimmunity. As for other experimental models, adrenalitis was induced in histocompatible recipients by adoptive transfer of lymph node cells from animals with adrenal autoimmunity. Modern immunogenetic studies are lacking, but there was a suggestion that some inbred strains may be more susceptible than others to the induction of experimental adrenalitis. More recently, adrenalitis and adrenal antibodies have been detected in BALB/c nu/nu mice reconstituted with thymic rudiments from young rats. The same mice also had thyroiditis, oophoritis or orchitis, i.e. were good models of autoimmune polyendocrinopathies.

Pathogenesis

Immunologically mediated lesions of the adrenal cortex may occur in a variety of ways. Adrenal parenchyma may be affected by a slow destructive process and is gradually replaced by connective tissue, with eventual loss of physiological function. The mechanisms involved may be cellular or humoral (autoantibody- and/or cytokine-mediated). The role of T lymphocyte-mediated cytotoxicity in Addisons disease is still unclear. Antibody-dependent cytotoxic destruction of adrenal cells might occur in several ways (phagocytosis or lysis of antibody-coated adrenal cells, antibody-dependent cellular cytotoxicity, immune complex-mediated reactions, inhibitory effects on steroid-producing enzymes). However,

babies born to mothers with autoimmune Addisons disease and circulating IgG antibodies to adrenal antigens develop none of the manifestations of the maternal disease during the neonatal period, despite the transplacental passage of adrenocortical antibodies. The role of cytokines and oxygen radicals in adrenal cortex damage is still relatively unexplored. Finally, the suggestion that antireceptor immunity may play a role in Addisons disease has not yet been confirmed.

Etiology

The cause(s) of autoimmune Addisons disease is(are) still unknown. Expression of MHC class II antigens, suggested as a key event in the initiation and/or maintenance of organ-specific autoimmunity, occurs in normal adrenals and, therefore, is unlikely to be the primary etiologic event of Addisons disease. Defects in HLA-DQB chain, found in IDDM, have not been reported in patients with Addisons disease. On the other hand, a deficiency of T suppressor cell activity was noted by some authors. To date, restricted T cell receptor (TCR) usage, alterations of the idiotypic-anti-idiotypic network and changes in the balance of the cytokine network have not been demonstrated in autoimmune Addisons disease.

Environmental agents (e.g. microorganisms and/or xenobiotics) might cause adrenal autoimmunity by

modifying autoantigens (so that they are no longer recognized as self), releasing tissue components normally absent from the circulation, or sharing antigens with tissues (molecular mimicry). In addition, they could inhibit T suppressor cells, stimulate T helper cells, B cells or macrophages, interfere with the idiotypic-anti-idiotypic network, alter tissue MHC expression and finally cause changes in the production of cytokines and lymphokines. However, none of these possibilities have yet been demonstrated in autoimmune Addisons disease.

AFFINITY

Bertrand Friguet, Lisa Djavadi-Ohanian and Michel E Goldberg, Unité de Biochimie Cellulaire, Institut Pasteur, Paris, France

The affinity (K_A) is a thermodynamic parameter that quantifies the strength of the association between two molecules in solution. For antibody-antigen complexes, K_A can be interpreted rigorously only for an equilibrium in solution involving a single species of antibody-combining sites and a single species of antigenic sites. Consequently, for polyclonal antibodies which contain a mixture of antibodies, no true affinity can be defined. The affinity of an antibody for an antigen depends on the structural complementarity of the binding site on the antibody (paratope) and the binding site on the antigen (epitope). Antibodies have a wide range of affinities that are generally between 10^5 (low affinity) and 10^{12} M^{-1} (high affinity). The overall stability of the complex between an antibody and an antigen is expressed by the term 'avidity' and is governed by

the affinity, the valency of the antibody and the antigen and the steric hindrance of the interacting components. Small changes in antigen structure can affect the strength of the antibody-antigen interaction. Similarly, changing the structure of the binding site of the antibody may alter the affinity of the antibody for the antigen. For instance, the progressive increase in affinity that occurs with time upon immunization (affinity maturation) arises from mutations in the complementarity-determining regions that build the paratope. Thus, antibodies that are different in their binding site structure are expressed and cells producing antibodies with higher affinities are stimulated preferentially to divide.

Definition and theoretical aspects

The antibody site to antigenic site association reaction at equilibrium can be written as:

with the concentrations of free antibody sites, free antigen sites and complex (saturated antibody or antigen sites) at equilibrium given as $[Ab]$, $[Ag]$ and $[x]$ respectively.

The affinity, K_A , is defined by the Law of Mass Action as:

$$K_A = [x]/[Ag].[Ab]$$

The concentration of antibody sites $[Ab]$ and the antigen sites $[Ag]$ at equilibrium are related to the total antibody sites $[Ab_t]$ and the total antigen sites $[Ag_t]$ by:

$$[Ab] = [Ab_t] - [x]$$

$$[Ag] = [Ag_t] - [x]$$

If $[Ag_t]$ is varied while $[Ab_t]$ is kept constant:

$$1/K_A = K_D = [Ag] ([Ab_t] - [x])/[x]$$

with K_D defined as the equilibrium dissociation constant.

Consequently

$$[x]/[Ab_t] = [Ag]/([Ag] + K_D)$$

Several linear plots have been proposed for the determination of K_D , the most commonly used of which are the Scatchard equation:

$$[x]/[Ab_t][Ag] = (1 - x/[Ab_t])/K_D$$

and the Klotz equation:

$$[Ab_t]/[x] = K_D/[Ag] + 1$$

If Ab_t and Ag_t are known, the experimental determination of K_D (or $K_A = 1/K_D$) requires precise measurement of only one of the three concentrations $[Ab]$, $[Ag]$ or $[x]$ (Figure 1).

K_A depicts an equilibrium property and therefore does not reflect the speed at which equilibrium is reached. Yet, K_A does depend on the association and dissociation rate constants. When binding is a simple one-step reaction, K_A is equal to k_{on}/k_{off} , where k_{on} and k_{off} are the association and dissociation rate con-

Figure 1 $(x)/(Ab_t)$ is usually referred to as v and corresponds to the fraction of bound antibody sites at equilibrium. (Ag) corresponds to the concentration of free antigenic site at equilibrium. (A) Scatchard plot; (B) Klotz plot.

stants. However, when a significant conformational change of either the monoclonal antibody or the antigen occurs upon binding, important deviations from that simple equation can be observed. For such cases, measuring only k_{on} and k_{off} would provide an erroneous estimate of the affinity.

The true affinity cannot be determined for antibody-antigen interaction in heterogeneous phase systems. No straightforward thermodynamic theory describes the equilibrium in heterogeneous phase systems, such as the binding of a monoclonal antibody to an antigen present on a cell surface or immobilized on an ELISA plate or a biosensor chip. K_A is defined in solution, with both the monoclonal antibody and the antigen diffusing and rotating freely in solution, while in the solid phase assay one partner is immobile. This can result in estimates of K_A by solid-phase assay being orders of magnitude away from the real affinity in solution. In such cases, the strength of monoclonal antibody-antigen interaction is best described by an appropriate operational parameter that is dependent of defined experimental conditions. Moreover it is now well established that immobil-

ization of either antibody or antigen often results in a partial denaturation of the protein, thus modifying its binding properties.

Methods for affinity measurement

As already pointed out, affinity is measured when the equilibrium between the two molecules has been achieved in solution. Hence, measuring K_A for monoclonal antibody and its antigen consists in mixing the monoclonal antibody (mAb) and the antigen at various initial concentrations, letting the equilibrium be established, measuring the concentrations of free and saturated sites at equilibrium and analyzing the binding curve. The experimental difficulty resides in distinguishing the free and bound state of either the monoclonal antibody or the antigen. Several methods can be used, such as equilibrium dialysis, radioimmunoassay (RIA) using precipitation with salts and other agents, filtration, fluorescence measurements and RIA- or ELISA-based methods. Equilibrium dialysis is the method of choice for hapten and dialyzable antigen but is not applicable for macromolecular antigens. Radioimmunoassays require radiolabeling of the antigen which may alter the binding properties of the antigen. Precipitation or filtration methods need the complex to be stable enough during the time required to achieve its separation so that the equilibrium is not disrupted. The use of fluorescence to determine K_A requires that either the monoclonal antibody or the antigen be fluorescent, and that a change in fluorescence should occur upon formation of the monoclonal antibody/antigen complex. The fluorescence signal used can be either intrinsic (e.g. tryptophan residues from the antibody and, possibly, from the protein antigens; some prosthetic groups such as pyridoxal-phosphate, NADH, NADPH, flavins, etc.) or result from prior fluorescent labeling of the antigen or the antibody with a fluorochrome. The fluorescent change observed upon association may be one of the following: excitation or emission wavelength shift, fluorescence quenching, fluorescence transfer, change in fluorescence polarization. As already underlined for radiochemical labeling, adding an extrinsic fluorescent label may affect the binding characteristics of the antigen or the antibody, either by steric hindrance or through a change in conformation, thus modifying the K_A . The sensitivity of current fluorimeters sets a higher limit of 10^8 – 10^9 M^{-1} on the K_A that can be determined. Some mAbs have much higher affinities for their Ag. Several methods such as indirect ELISA or surface plasmon resonance using immobilized antigen or monoclonal antibody have been developed to determine values of the affinity.

Such measurements yield real values of K_A only rarely. Friguet and colleagues have defined a procedure to measure by a competition ELISA method the real association equilibrium constant in solution. This method requires no labeling of either the antigen or the antibody, which ensures that the affinity is characteristic of native antibody and antigen. This method gives access to affinity constants as high as 10^{10} – 10^{11} M^{-1} and can be used for studies on protein–protein interactions that do not involve antibodies. Since this method has been frequently used for affinity determination, its principle is described in the next paragraph.

Affinity measurement in solution by competition ELISA

In the competition ELISA the monoclonal antibody at a fixed concentration and the antigen at varying concentrations are first incubated in solution until the equilibrium is reached. Then, the concentration of the free (i.e. not associated with antigen) monoclonal antibody at equilibrium is determined by a classical indirect ELISA using antigen-coated plates.

For correct determination of the free antibody concentration at equilibrium, several requirements must be fulfilled: 1) The absorbance obtained in the last step of the indirect ELISA, which reflects the free antibody concentration, must be proportional to the antibody concentration tested. 2) Only a small percentage of the free antibody molecules (i.e. less than 10%) must bind to the coated antigen, to prevent any significant disruption of the equilibrium in the liquid phase. This ensures that, during the ELISA, the equilibrium in solution is not significantly modified. By this means, the observed equilibrium constant corresponds to the real affinity. 3) Since the association constant K_A is generally dependent on the temperature, the temperature must be kept constant throughout.

To satisfy requirements (1) and (2), it is necessary in previous ELISA experiments to determine the total (i.e. initial) antibody concentration range that must be used, the concentration of the coated antigen and the optimal incubation time of the antibody solutions in the coated wells. The state (native or partially denatured upon coating) of the coated antigen and whether or not it is recognized by the mAb differently from the soluble antigen is not important as long as the coated antigen can specifically and quantitatively trap the free antibody.

An example of affinity determination by the competition ELISA method described above is given in Figure 2 using a computerized fitting program.

The multivalency of antibodies and antigens

Figure 2 Saturation curve in solution of a monoclonal antibody by its antigen: $[X]/[Ab] = [Ag]/([Ag] + K_D)$. The value of K_D (1.5×10^{-9} M) was directly extracted with a computerized non-linear regression method.

sometimes complicates the determination of affinity. The distortion of the saturation curves (as compared with simple binding) caused by the multivalence of immunoglobulins in indirect competition ELISA was first analyzed by Stevens and has become the object of much attention. However, the simple data analysis initially proposed by Friguet and colleagues provides satisfactory results when divalent immunoglobulins are used, provided one extracts the affinity only from the part of the saturation curve obtained at high saturation of the monoclonal antibody by the antigen.

Why is affinity important?

The affinity is of considerable importance in understanding the biological activity of antibodies. For instance, when the immune system is challenged with antigen, the immune response and host defense is evaluated by the affinity of the antibodies. However, immune sera contain a mixture of antibodies with different affinities and the experimental conditions can considerably influence the apparent affinity. It is now well established that in the commonly used competition ELISA, the conditions must be carefully selected to minimize disruption of the liquid-phase equilibrium by the solid-phase antigen. In the case of a polyclonal serum-containing antibodies with widely different affinities, it is practically impossible to simultaneously fulfil this requirement for all the antibodies under a unique set of experimental conditions. Schematically, low-density coating of the antigen will trap essentially high-affinity antibodies, resulting in the determination of the apparent affinity of only these molecules, which will not be representa-

tive of the average affinity of the serum. In contrast, high-density coating of the antigen will trap low-affinity antibodies too, but the trapped fraction of high-affinity molecules will be large and their contribution to the average affinity will be seriously biased by the disruption of the equilibrium. The knowledge of antibody affinity and specificity for its antigen determines its reliability and usefulness as a reagent in a variety of immunochemical techniques such as histoimmunochemistry, immunochemical labeling of cells or cellular components, immunodetection by ELISA, RIA or western blotting. Most often, strict specificity and high affinity are a prerequisite for the accuracy of these techniques. However, it is sometimes useful to have antibodies of moderate affinity available as in the case of purification by immuno-adsorption which needs, as a final step, the immuno-complex to be dissociated.

Since the affinity of a monoclonal antibody for a protein depends on the structural complementarity of the binding sites on the two molecules, changes in affinity can reflect changes in protein structure occurring at the site recognized by the antibody. Thus, thoroughly characterized monoclonal antibodies have been used as probes to detect and analyze conformational changes within proteins.

AFFINITY CHROMATOGRAPHY

George L Mayers, Department of Molecular Immunology, Roswell Park Memorial Institute, Buffalo, New York, USA

Carel J van Oss, Department of Microbiology, School of Medicine, State University of New York at Buffalo, Buffalo, New York, USA

Affinity chromatography is the process by which the reversible biospecific interactions between a molecular species and its ligand are used in the isolation of that molecular species from a biological milieu. Conceptually the process is extremely simple. The ligand is attached to a solid support to form a specific adsorbent to which the biological system, usually in the form of a homogenate or extract containing the molecular species of interest, is exposed. Only the molecular species that shows appreciable affinity for the ligand will be retained or retarded; other materials which have no specificity for the insolubilized ligand will pass through the column. The molecular species that has become attached to the adsorbent must then be eluted without destroying its biological properties.

Unlike many of the other isolation techniques that depend upon differences in physical properties of the biological materials to effect a separation, the use of affinity chromatography takes advantage of functional properties of the system. Since almost all biological processes depend on specificity between different molecules, affinity chromatography has found a wide range of applications and new ones are always being developed. These include the use of antibiotics, antibodies, antigens, chromophores and dyes, coenzymes, drugs, hormones, enzymes, inhibitors, lectins, nucleic acids, nucleotides, polynucleotides, substrates and substrate analogs, sugars and polysaccharides, tRNA, and vitamins to isolate macromolecules, organelles, viruses and cells.

Successful application requires that the interactions between the biological molecules and their ligands have an affinity that is at least 10^5 , but not so strong that the binding cannot be reversed without

detriment to the biological materials of interest. Thus the preparation of appropriate ligand conjugates often requires a considerable amount of extra work, but, when successful, the results can be dramatic. The exquisite sensitivity of this system has allowed application to the separation of large protein assemblies involved in signal transduction, transcription complexes and cytoskeletal structure. The technique of affinity chromatography is one of the few procedures that will usually achieve a major purification in one or two steps, often producing an homogeneous sample for study. In addition the process is effective for extremely dilute solutions and allows extensive concentration of the biological sample. Such a dramatic example of the use of affinity chromatography is the successful isolation of 6.26 mg, a 12% yield of transcobalamin II from 1400 liters of human plasma.

Historical perspective

The earliest forms of affinity chromatography were actually developed by immunochemists. In 1951 Campbell, Luescher and Lerman developed antigen-cellulose columns for use in isolating specific antibodies, a separation that could not be achieved unless one could take advantage of the affinity of the antibody for its specific antigen. The conjugation of an antigen to a solid matrix was called an immuno-adsorbent and will be further described in the section on immuno-adsorbents. In 1968, Cuatrecasas, Wilchek and Anfinsen applied this concept to the isolation of enzymes and introduced the term affinity chromatography. Application of the technique exploded not only because the generality of the approach became clear, but also because a new solid

support based on agarose with appropriate chemistry for coupling many types of ligands was introduced. Since then this technique has had extensive application in all aspects of the biological sciences.

Recently, the use of affinity chromatography has been integrated with high-pressure liquid chromatography (HPLC) systems to combine the specificity of affinity chromatography with the speed and sensitivity of HPLC. This has been extended to include high-pressure immunoaffinity chromatography. One area that has been under-exploited is the use of specific antibodies to isolate biological materials such as growth factors that are produced at low concentrations in cell culture.

The procedure of affinity chromatography

Unlike the use of physical separation procedures, the use of affinity chromatography requires more extensive knowledge of the biological material and its binding to the ligand that will be used for isolation. The use of agarose has been the overwhelming choice for a solid support for attachment of ligands because of its hydrophilicity and thus low non-specific binding for most macromolecules, its good porosity and uniform spherical beads for preparing columns with suitable flow rates and good resolution, and its ability to be modified readily using cyanogen bromide to allow coupling of most important ligands either directly or via a linking molecule.

Ligand or ligand analogs must be selected that permit conjugation without significantly affecting the ligand's complementarity structure and thus detrimentally reducing its ability to bind the biological material. The attachment of the ligand may decrease or increase its affinity for the biological molecule depending on the nature of the linkage molecules and the conformational constraints induced by the coupling chemistry and the solid support, and these factors must be evaluated experimentally. For most isolations of macromolecules, the ligand-conjugated matrix is packed in a standard chromatography column, and the sample containing the biological molecules of interest is applied to the column. Biological materials that do not recognize determinants on the solid phase pass through, and the column is thoroughly washed with neutral buffers to remove all nonspecifically attached materials. Since the commonly used cyanogen bromide coupling chemistry introduces an isourea group at the linkage point which has a $pK_a = 10.4$, there are positive charges in the matrix, and these columns tend to have some weak ion exchange properties. Some of the commercially available supports have attached suitable func-

tional groups for coupling while avoiding the introduction of a charged moiety. However, if a protein such as albumin is used for linking the ligand, there is often increased weak binding between some of the impurities and the column. The amount of these weaker binding contaminants can be reduced by washing the column with higher ionic strength buffers, 1 or 2 M NaCl in borate or phosphate at pH 7–8, or 0.5 M carbonate buffer at pH 9.0 as long as they do not also elute any of the specific material.

Following removal of impurities and nonspecifically attached materials, conditions are changed to effect an elution of the desired biological molecules in their native state. Since the binding results from noncovalent interactions that include electrostatic, hydrophobic, and van der Waals forces, solvent changes must be made to reduce these interactions or compete with the ligand on the matrix to release the sample from the column without denaturing the macromolecule. The most commonly used method of elution is to reduce the pH to 2.8 with glycine-HCl buffer or 1 M propionic acid. If that fails to elute the sample or those conditions denature the protein, the use of alkaline conditions often yields better results. Probably the best alkaline buffer is 0.1 M diethylamine which has a pH of approximately 11. Many anti-idiotypic antibodies and some antibodies to protein determinants seem to prefer these elution conditions to the use of acid. In a number of cases, when a secondary antigen-antibody interaction (which usually is of the 'hydrophobic' variety) has set in, in addition to an increase in pH, a lowering of the surface tension of the medium should be effected at the same time by means of the admixture of a water-miscible organic solvent with strong hydrogen-acceptor properties, such as ethylene glycol, dimethylsulfoxide (DMSO, approximately 30–50%), or propanol (approximately 3–10%). Elution of various blood group antibodies from red cells can be effected at pH 9.5–10.0, in the presence of $\approx 47\%$ DMSO. Elution of DNA-specific antibodies from immobilized DNA (which is a preponderantly electrostatic system) can usually be effected by just a pH increase to 11 (for low-affinity antibodies), or 12 (for high-affinity antibodies), using glycine buffers. In the relatively rare cases where Ca^{2+} bridging is the main mechanism of antigen-antibody binding, elution is best done with Na_2EDTA , or other complexing agents. The protein should be maintained in the unfavorable conditions for as short a time as possible and should be kept cold during such procedures. The use of ligands can be very effective, but it is sometimes difficult to remove the ligand completely from the sample. The use of strong denaturants such as guanidine-HCl, urea and SDS should usually be

avoided since it is often difficult to recover the biological sample in a native state, although these reagents can be effective in regenerating the column for reuse. In those cases where the antigen and/or antibody do not become irreversibly denatured by some of the more robust dissociating agents, and those cases where an affinity column or surface has to be regenerated regardless of the fate of the eluate, the most efficient eluants are: 10 mM HCl (no salt or other additive), pH approximately 2; 50 mM NaOH (pH 10); or 50 mM NaOH together with 15–30% acetonitrile. These eluants have been found effective in regenerating antigen- or antibody-coated surfaces in the bioaffinity sensor apparatus.

Besides the use of affinity chromatography for specific interactions, there are many examples of using ligands to isolate a restricted family of biological molecules. Protein A and, more recently, Protein G can be used to isolate a large number of immunoglobulin subclasses from a variety of species and have found extensive use in the isolation of monoclonal antibodies. Hydrophobic columns have found application for membrane proteins; Cibacron Blue 3GA and related dyes have found restricted applications such as removal of albumin from serum. With more readily available molecular models of protein-binding sites, efforts have been made to design analogs of these textile dyes that would have higher specificity for the protein of interest. The use of metal chelate columns has permitted separations based on very subtle differences in amino acid residues, and sequence-specific DNA affinity chromatography allows the isolation of DNA-binding proteins important in regulating transcription and replication. Thus, affinity chromatography has made a major impact on the procedures used to isolate specific substances in all areas of biology and medicine.

AFFINITY LABELING

David Givol, Department of Molecular Cell Biology, Weizmann Institute of Science, Rehovot, Israel

Meir Wilchek, AFRC Institute for Animal Health, Pirbright Laboratory, Pirbright, Woking, Surrey, UK

Biological processes are catalyzed and regulated by the specific interactions between corresponding molecular species. The strength of interactions reflects the affinity between the molecules. The affinity is determined by the sum of the reciprocal interactions between the components in a given biological system. In biology, the proteins are the most prominent ligand-binding molecules. Whether we consider enzymes, immune proteins, receptors or transport proteins, the key step in their biological function is the specific recognition and binding of a ligand (substrate, antigen, hapten, hormone, etc.). A small, and in many cases well-defined, part of the total surface of the protein is presumed to be involved in this selective, high-affinity interaction with the specific ligand, and this part of the molecule is referred to as the binding site. Affinity labeling is one of the effective means of studying the binding site.

Affinity labeling and photoaffinity labeling

Affinity labeling is a technique for labeling the binding (or active) site of proteins by virtue of a ligand analog to which a chemically reactive or photoreactive group has been attached. The latter can form a covalent bond with a suitably oriented amino acid in the binding (active) site. Such a labeling reagent ($R-L$) would consist of 1) a biologically active substance (R) capable of forming a reversible complex with a given protein (P), and 2) a properly positioned, chemically or photochemically reactive leaving group (L) (**Figure 1**). Upon incubation, the affinity label interacts with its protein counterpart, resulting in the formation of an irreversible protein-ligand complex. This process is illustrated in **Figure 1** and described in the following formula:

Figure 1 Affinity labeling.

The formation of the initial reversible complex ($P \cdots R-L$) increases the local concentration of the reagent at the active site relative to its concentration in solution. This ensures that the labeling reaction will take place at the binding site and not elsewhere. Following the formation of the reversible complex ($P \cdots R-L$), a functional group(s) on the protein adjacent to the active site reacts chemically with the affinity label, resulting in a covalent bond to form $P-R$. The affinity-labeled protein is either totally or partially inactivated by virtue of covalent bond formation.

The experimental criteria for a good affinity label are stipulated as follows: 1) its reaction with a given protein should result in a concomitant inactivation of the reversible binding activity; 2) it should not significantly label unrelated proteins; 3) specific ligands should protect against the affinity labeling; 4) it should facilitate the localization of the covalently bound ligand at the active site of the protein.

In planning an affinity labeling reagent, one should ensure that the reactive group (L) is relatively small and does not interfere significantly with the protein-ligand interaction. One should also consider the availability of radioactively labeled precursors and the facility of synthesis and stability. Finally, the labeled residue should remain stable to degradative techniques in order to permit its identification.

The first demonstration of affinity labeling by deliberate design was accomplished in 1961. Although affinity labeling was originally developed for investigations of purified enzymes, it has also added significantly to the study of the structure of active sites in other systems – for example, antibodies, ribosomes and membrane receptors. Affinity labeling of active transport carriers and hormone receptors has been used to identify and isolate these systems.

Affinity labeling of the antibody combining site

Antibodies and myeloma proteins against haptens comprise the most commonly used experimental system in which the determination of the antibody structure-function relationship has been attempted. Affinity labeling studies of antibodies were initiated by Singer, Wofsy and Metzger using diazonium

labeling reagents attached to a benzene arsonate hapten. Converse and Richards used diazoketones attached to dinitrophenyl (DNP) haptens as affinity labels, while Givol, Wilchek and coworkers used bromoacetyl derivatives attached to DNP haptens to label DNP-specific antibodies and MOPC 315 (a myeloma protein that binds DNP). A homologous series of reagents was prepared in which the bromoacetyl group was attached to the DNP hapten at progressively increasing distances from the haptenic moiety, thus allowing the labeling of residues in the combining site at various distances from the DNP ring. A photoaffinity label using aromatic azides was introduced by Porter's group. The photoaffinity reagent was introduced to overcome the limitations of the other reagents which can interact only with electrophilic reagents; the azide reacts with any amino acid residue. In addition, the design of this reagent made the chemical reactive group (L) part of the hapten.

Major results obtained

The results derived from affinity labeling studies of antibodies and myeloma proteins from different species that have different ligand specificities were surprising in their consistency.

1. Both light and heavy chains of the antibodies were labeled using affinity labeling reagents. With homogeneous myeloma proteins, it was possible to design reagents such that either the light or heavy chain could be labeled. Particularly interesting information was obtained with the homologous bromoacetyl derivatives of DNP ligands and the MOPC 315 protein. For example, it was shown that *N*-bromoacetyl-*N'*-DNP-ethylenediamine exclusively labeled tyrosine 34 on the light chain, whereas *N*^α bromoacetyl-*N*^ε-DNP-L-lysine labeled lysine 54 on the heavy chain. These experiments demonstrated that both chains contribute contact residues to the antibody-combining site.
2. Affinity labeling studies on antibodies derived from different species using five different reagents showed that the labeled residues were confined to three major stretches of the NH₂-terminal variable region, i.e. around positions 30, 55, 90 in either the light or heavy chain. These results clearly indicated that three restricted segments of both chains actually constitute the specific combining site. This was fully supported by independent evidence, e.g. the identification by statistical analysis of hypervariable segments (CDR) in the V region and by the isolation of the Fv fragment which provided final direct

proof that the combining site is entirely formed by the variable regions. X-ray crystallography of Fab-hapten complexes supported and extended this picture.

Affinity cross-linking

One outcome of affinity labeling using the homologous series of bromoacetyl derivatives, which labeled different residues of the light and heavy chains, was that it enabled the first demonstration of affinity cross-linking by a reagent which contained two bromoacetyl groups and a DNP moiety. This reagent cross-linked the heavy and light chains at the correct positions. Affinity cross-linking is today a major tool in biology and immunology for the identification, localization and isolation of receptors. This is usually accomplished by using a radioactive ligand that is allowed to bind to its receptor, after which a general cross-linking reagent is applied. Alternatively, a ligand to which a photoreactive group has been attached can be used; after binding to the target membrane, light is applied which establishes a covalent bond at the site of binding. Affinity cross-linking allows the identification of the labeled receptor and determination of its size by gel electrophoresis. Because it makes use of a cross-linker which is separate from the ligand, it can be applied to large complex ligands such as growth factors and other proteins. Examples of the use of affinity cross-linking in the immune system are interleukin-2 and its receptor, Fc and receptor, major histocompatibility complex (MHC) class II molecules and nominal antigen peptides on antigen-presenting cells, and photoreactive vinblastine and the 170 kDa protein from multidrug-resistant human cancer cells. Affinity cross-linking is mainly used to identify the molecular size and cellular localization of receptors. Its use, however, can be extended to study the ligand-binding site of the receptor, as has been shown for the epidermal growth factor receptor.

Immunoaffinity chromatography

Another outcome of the affinity labeling studies was the development of immunoaffinity chromatography. The localization of the modified residues in the antibody sequence requires the isolation of the labeled peptides. Givol and Wilchek introduced the immobilized antibody, with the same specificity as the labeled antibody, to 'fish out' the labeled peptides. Thus, peptides that were labeled with the DNP group could be isolated on a DNP-specific antibody column and peptides labeled with diazoarsonate were similarly isolated on an anti-phenylarsonate column. Immuno-

affinity chromatography on immobilized monoclonal and polyclonal antibody columns is the most useful approach today to isolate biologically active proteins prepared by recombinant technology and for purification of other proteins which have no known ligands. For example, a commercial preparation of human factor VIII utilizes an insoluble antibody column.

Conclusion

The most significant contributions of affinity labeling have been in the elucidation of structure–function relationships of the active site of a given biological system. For antibodies, affinity labeling provided structural information regarding the binding site before the X-ray structure was known. The techniques that have evolved from these studies are very important tools in modern biology and will continue to be so in the future. It is hoped that refined information regarding binding sites in various complex biological systems will revive the initial impetus which led to the development of affinity labeling as a method: namely, the potential for designing better and more effective drugs. Such drugs may inactivate receptors or intracellular enzymes via affinity labeling.

AFFINITY MATURATION

Klaus Rajewsky, Institute for Genetics, University of Cologne, Weyertal 121, Köln, Germany

The changes of antibody quality in the course of the antibody response is a classical immunological phenomenon. One such change is the gradual increase of antibody affinity for the immunizing antigen with time, called affinity maturation. Affinity maturation is typical of, and regularly observed in, T cell-dependent responses and is a key feature of immunological memory in B cells. Upon secondary immunization with a T cell-dependent antigen an anamnestic antibody response is produced, consisting of antibodies with a higher affinity than that of primary response antibodies.

Burnet's clonal selection theory provided a theor-

etical framework for affinity maturation, as shown in **Figure 1**. The B cells in the peripheral B cell pool express a clonally distributed, diverse antibody repertoire. This repertoire includes antibody specificities against any given antigen or antigenic determinant, but, in general, high-affinity antibodies should be less frequent than antibodies of average or low affinity. The clonal selection theory postulates that antigen selectively expands B cells expressing antibodies on their surface to which it can bind. With decreasing antigen concentration in the course of the response this mechanism results in the preferential expansion of B cells expressing high-affinity antibodies, as depicted in the upper part of **Figure 1**. We have

Figure 1 Models of affinity maturation. (Taken, with modification, from Rajewsky K (1989) *Progress in Immunology* 7: 400.)

learned in the meantime that the process of B cell triggering is more complex: the B cell captures antigen by its receptor antibody from antigen-presenting (follicular dendritic) cells, processes it intracellularly and exposes fragments of the antigen on its surface, in the groove of major histocompatibility complex (MHC) antigens of class II. Subsequently, T helper cells recognize the antigen-loaded MHC molecules and signal the B cell into its pathway of proliferation and differentiation. This multistage process, together with the variability of antigenic valency, makes the relation of antibody affinity to cellular selection complicated (indeed selection seems sometimes driven by the on-rate of antigen binding rather than affinity), but does not change the picture in principle.

The model depicted in the upper part of **Figure 1** is in line with experimental evidence that the B cell clones dominating secondary and hyperimmune responses to a given antigen often differ strikingly from those dominating the primary response in terms of antibody variable (V) region gene usage. However, it has become clear that the central mechanism of affinity maturation is not the selection of rare, pre-existing high-affinity antibodies, but a process of somatic evolution, in which somatic antibody mutants are generated at high rate as a consequence of antigenic contact and high-affinity mutants subsequently selected by antigen (**Figure 1**, lower part). It is often forgotten that Burnet considered this possibility already in his clonal selection theory: 'The . . . postulate, that active sites on cell surface or globulin molecules can be modified to a wider reactivity by somatic mutation, provides the chief agent to allow change in antibody character as immunization proceeds. If the primary postulates of the clonal selection theory are accepted, such a result of somatic mutation is as much in order as any other'. The tools

of molecular biology allowed this possibility to be studied directly, by isolating and sequencing antibody V genes expressed by B cells participating in model immune responses. Initially, the V genes were identified in hybridoma cells selected from various stages of the immune response. They can now be isolated from the overall B cell population or even single B cells by specific gene amplification, using the polymerase chain reaction. These experiments demonstrated that, within a short time after priming with a T cell-dependent antigen, the initial repertoire of germ line-encoded antibodies is completely changed into a repertoire of somatic antibody mutants as they are exclusively seen in secondary and hyperimmune responses. This is achieved by a mechanism introducing somatic point mutations into rearranged antibody genes at an exceedingly high rate, estimated to be in the range of 1×10^{-3} per base pair per generation. The mutations are introduced in a stepwise manner in the course of cellular proliferation and mutants expressing high affinity for the antigen are selected out in a highly efficient manner, preventing the accumulation of mutants expressing useless, potentially harmful (autoaggressive) specificities. Genetic engineering experiments have directly demonstrated that certain key mutations, often repeatedly seen in the repertoire of antibody mutants as it arises after immunization with a given antigen, are directly responsible for an increase of affinity for the antigen. However, because of the high rate of somatic mutation the antibodies also harbor a multitude of mutations which are not affinity selected (e.g. 'silent' exchanges). Affinity maturation through somatic hypermutation occurs in a particular B cell differentiation pathway, namely the proliferation of B cells and their maturation into memory or plasma cells in germinal centers. In this pathway the

hypermutation mechanism (whose molecular basis remains to be elucidated) is turned on through an unknown (T cell-derived?) signal and is later turned off to allow the stable expression of the affinity-matured secondary antibody repertoire.

Taken together, affinity maturation of antibodies is mainly based on a process of somatic evolution in which somatic antibody mutants are generated at high rate upon T cell-dependent immunization, and high-affinity mutants selected by antigen. This allows the antibody system to rapidly adapt to any given immune stimulus – the key requirement of acquired immunity. Only in this way will the system be able to deal efficiently with microbial infection, in the course of which mutants of the infecting agent often accumulate rapidly, threatening to circumvent immune protection.

AFRICAN SWINE FEVER

Michael S Denyer and **Philip J Wilkinson**, Institute for Animal Health, Pirbright Laboratory, Pirbright, UK

African swine fever (ASF) is a highly contagious acute hemorrhagic disease of domestic pigs caused by a large icosahedral DNA virus which produces a wide range of clinical signs. Protective immunity can be stimulated *in vivo* but classical neutralizing antibodies have not been demonstrated. The complete genome has been sequenced and some proteins that could enable the virus to evade the host immune response have been identified. There is no vaccine.

Characteristics of the organism and its antigens

The virus persists in the southern half of Africa, either in wildlife reservoirs – wart hogs and soft ticks (*Ornithodoros moubata*) – or as an enzootic disease of domestic pigs. After more than 30 years as an enzootic disease in domestic pigs in southern Europe it has been eradicated from Portugal (1993) and

Spain (1995). Because it has icosahedral symmetry and replicates in the cytoplasm of infected cells, ASF virus was originally classified as an iridovirus but the genome structure and replication strategy differ substantially from the Iridoviridae and are more like the Poxviridae. The virus is currently classified as the only member of a family called African swine fever-like viruses. The entire genome of a tissue culture-adapted Spanish isolate has been sequenced; it is 170 101 nucleotides long and contains 151 open reading frames which include five multigene families of unknown function.

The only cells in the pig in which ASF virus is known to replicate are those of the mononuclear phagocytic system in which virus produces hemadsorption (HAD) of pig erythrocytes to a CD2 homolog expressed on the cell surface (Figure 1).

Infection occurs by receptor-mediated endocytosis via saturable binding sites; it has been shown that

Figure 1 Hemadsorption to an alveolar macrophage infected with the Malawi isolate of African swine fever virus. The red blood cells (rbc) adhere to the surface of the infected cells producing a classical rosette. The viral structures include the perinuclear virus factory (vf) containing virus particles at various stages of assembly and cytoplasmic virus (arrow heads) prior to leaving the cell by budding. Cell nucleus (n). The bar represents 5 μ m. (Provided by S.M. Brookes).

one receptor-binding protein of the virus is a low molecular weight protein (12 kDa) expressed as a homodimer (17 kDa).

Virus is released from infected cells by budding and acquires an external lipoprotein envelope containing glycosylated components; extracellular virus does not contain glycoproteins. The virus contains over 50 structural proteins, the most highly conserved of which are good immunogens and are used as antigens for serological tests to detect virus. There is no clear identification of virus strains by traditional serological methods but some differentiation is possible by monoclonal antibodies and antibodies that inhibit HAD. There is evidence that field isolates contain viruses with variable polypeptides, that these may also vary on passage in pig macrophages and that there is a complex variety of virus serotypes. Different and distinct genotypes have been identified by restriction enzyme analysis.

Immune response of the host

Circulating antibodies in infected pigs can be detected by radioimmunoassay or ELISA 3–4 days after infection and they persist for life. Neutralizing antibodies have never been demonstrated. After recovery from infection with less virulent isolates, pigs are persistently infected for at least 6 months and are resistant to challenge with homologous virus, although the challenge virus may undergo limited replication without producing clinical disease; they are usually fully susceptible to infection with different virus genotypes.

Pigs given passive antibody or piglets given colostrum antibody have reduced levels of virus in the blood and tissues when challenged with virulent virus and show little or no clinical signs of disease. Studies *in vitro* have also shown that antibodies can reduce virus yield from infected pig macrophages in the absence of complement but the transfer of immune lymphocytes has no effect on the course of disease.

Antibodies which mediate lysis of ASF virus infected pig kidney cells (IBRS2) *in vitro*, by either antibody-dependent cell-mediated cytotoxicity (ADCC) or complement-mediated lysis, are present in serum 12–14 days after infection but are not able to lyse infected pig macrophages.

Because the humoral immune response does not appear to mediate the immunity of pigs which recover from infection, the cell-mediated immune responses have been investigated to determine what immune mechanisms may be important, and the following observations have been made.

Natural cytotoxic cells are also unable to lyse infected macrophages but may be important as producers of interferon γ (IFN γ). Some isolates of ASF virus can induce IFN γ production, and recombinant bovine IFN α and porcine IFN γ reduce infectious virus production by pig alveolar macrophages and monocytes *in vitro*.

Stimulation of peripheral blood lymphocytes from uninfected pigs with recombinant porcine interleukin 2 (IL-2) will induce a lymphokine-activated killer (LAK) cell which will lyse infected pig macrophages. Lymphocytes from recovered animals stimulated with ASF virus *in vitro* will produce IL-2, which indicates that a lymphokine-activated cytotoxic lymphocyte may be involved. ASF virus-specific cytotoxic T lymphocytes obtained from infected inbred pigs with defined SLA haplotypes are major histocompatibility complex (MHC) class I restricted.

Evasive strategies by the organism

The interaction of ASF virus with the host cells and its immune system and the processes involved in producing disease are still poorly understood; however, the complete genome sequence has indicated that some novel strategies may be employed to avoid the immune response, by direct and indirect effects of the virus on the cells of the immune system, in the absence of neutralizing antibody.

ASF virus replication in pig macrophages, and the release of immune mediators, may be important in aiding the virus to evade the immune system, in addition to being possible factors in the pathogenesis of the disease. Infection of pig macrophages does not

alter the expression of Fc receptors nor their ability to mediate ADCC of antibody-coated bovine erythrocytes but does modulate antibody-mediated phagocytosis and chemotaxis. A protein isolated from infected cells has been shown to have a strong immunosuppressive effect *in vitro*. Infection of these cells will cause the downregulation of the pro-inflammatory cytokines IL-8, IFN α and tumor necrosis factor α (TNF α) but not of TGF β .

The ASF virus genome also encodes for a Bcl-2 homolog which may aid the survival of infected cells and maintain persistence. In contrast, lymphocytes in infected tissues have been found to be apoptotic. Thus ASF virus may downregulate inflammation, increase the survival of infected cells and cause apoptosis of surrounding effector cells.

Although virus-specific delayed-type hypersensitivity, antibody production and lymphoproliferation are readily demonstrable, there are reports that the more virulent isolates can interfere with the immune response to foot-and-mouth disease virus in pigs inoculated with this virus 3 days after infection with ASF virus.

Vaccines

There are no commercial vaccines available for ASF. All attempts to produce suitable vaccines from either inactivated virus or viruses attenuated by passage in culture have been unsuccessful. There are reports in which a limited number of pigs were protected from death, but not clinical disease, after inoculation with

infected spleen treated with a nonionic detergent in Freund's complete adjuvant.

AGGLUTINATION

Abram B Stavitsky, Department of Molecular Biology and Microbiology, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA

A variety of particles bearing either natural or conjugated epitopes on their surfaces are specifically agglutinated by polyclonal or monoclonal antibodies to these epitopes. These particles can be inert but bearing these epitopes on their surfaces. They can also be large viruses, eukaryotic cells, or a variety of other cells, including bacteria, yeasts, fungi, protozoa and parasites. Inasmuch as very low concentrations of these antibodies can specifically agglutinate these cells, this reaction has served as a very sensitive and specific assay for the presence of specific antibodies in the serum or body fluids, e.g. antibodies to the bacillus of typhoid fever. The reaction can also be

employed for the detection and measurement of antigen in the serum or body fluids. Agglutination is rarely used in research and for diagnosis because it has not been possible to easily and precisely quantitate this reaction. Therefore, it has been replaced by more quantifiable assays for antibodies, including the ELISA (enzyme-linked immunosorbent assay), various radioimmunoassays and other types of immunoassays. More recently, however, methods which facilitate, speed up and make more precise the reading of agglutination reactions may eventually result in the more frequent use of this very sensitive reaction for both research and diagnosis.

History

Specific bacterial agglutination was first observed about 100 years ago by Charrin and Roger. *Pseudomonas pyocyanea* grown in the serum of an immunized animal yielded a clear supernate with clumps of microbes at the bottom of the culture tube, whereas organisms cultured in normal serum were uniformly distributed throughout the tube. Bordet was the first to suggest that specific agglutination could be used for the diagnosis of infectious diseases. Widal and Grunbaum in 1896 applied this reaction to the diagnosis of typhoid fever. Bordet and Gay made the first fundamental analysis of the mechanisms of this reaction.

Landsteiner and Ehrlich, and Morgenroth in 1890 independently observed that normal human sera agglutinated the erythrocytes of other individuals. They also found that the injection of human red cells induced the formation of antibodies which by agglutination could distinguish the blood cells of different individuals within the species. These observations formed the basis of blood typing for transfusion.

In 1951 Boyden reported that proteins are observed on tannic acid-treated erythrocytes and that these cells are specifically agglutinated by antiprotein sera. Battisto and Chase, in 1963, extended this passive hemagglutination method to the detection of antibodies to haptens by the absorption of soluble hapten-protein conjugates to tanned erythrocytes.

Coombs and colleagues detected 'incomplete' Rh antibodies by the use of a second antiglobulin reaction. Pickles showed in 1946, that these 'incomplete' antibodies specifically agglutinated enzyme-treated erythrocytes. Bozicevich and coworkers in 1951 adsorbed various antigens to bentonite particles and observed that these particles were then flocculated by specific antisera. In 1956 Singer and Plots demonstrated that human gammaglobulin-coated polystyrene latex particles could be used for the detection of rheumatoid factors in human sera.

Boyd and Renkonen independently reported in 1946 and 1947, respectively, that different seed extracts contained substances which selectively agglutinated the erythrocytes of various species through binding to particular polysaccharides on the cell surface. These plant proteins are called lectins.

Definitions and classification of agglutination reactions

Agglutination is defined as the formation of clumps of cells or inert particles by specific antibodies to surface antigenic components (direct agglutination) or

to antigenic components adsorbed or chemically coupled to red cells or inert particles (passive hemagglutination and passive agglutination, respectively). Erythrocytes are also agglutinated by nonantibody substances such as plant proteins, viruses, salts of heavy metals, inorganic colloidal acids and bases, and basic proteins (protamines, histones). Agglutination inhibition or hemagglutination inhibition refers to the inhibition of these reactions by soluble antigen which reacts with the combining sites of the antibodies and thereby prevents their binding to and agglutination of the particles.

Mechanisms of specific agglutination

Agglutination occurs in two stages: first, specific combination of antibody with antigen on the cell surface; second, formation of visible aggregates of the particles. According to Bordet, the antibody sensitized the cells to subsequent nonspecific agglutination by electrolytes but the alternative 'lattice' theory suggested that the cells were agglutinated through their specific linkage by bivalent or multivalent antibodies. The bulk of the evidence favors the 'lattice' theory, but under some conditions the second stage may be nonspecific so that cells of different antigenic specificities are coagglutinated in the presence of antibody to only one of the specificities. Usually, however, the second stage is also specific.

Agglutination may be influenced by many factors, including ionic strength (0.15 M sodium chloride is optimal), temperature (from 0 to 30°C agglutination is increased), and viscosity of the medium. Hemagglutination cannot be achieved with certain immunoglobulin G (IgG) class anti-protein or anti-blood group antibodies. Erythrocytes suspended in isotonic saline on account of mutual repulsion by negative zeta potential and intercellular attraction induced by van der Waals forces cannot approach each other more closely than 5–10 nm. The two valences of single IgG class antibodies are at most about 12 nm apart; therefore, they cannot bring the erythrocytes close enough together to agglutinate them. On the other hand the two diametrically opposed valences of the potentially decavalent IgM antibodies can easily bridge a distance of about 300 nm. Hemagglutination by IgG antibodies can be achieved by extending the IgG antibodies with anti-IgG antibodies or through the treatment of erythrocytes with enzymes which permits a much closer approach of the erythrocytes.

It seems paradoxical that agglutination often does not occur in the presence of the highest antibody concentrations. This is called the prezone or prozone phenomenon. This phenomenon may be due to the

coating of the antigenic particles with such large numbers of antibody molecules that the number of cross-particle linked antigen-antibody complexes is decreased. The presence of nonagglutinating or blocking antibodies or other nonspecific factors which inhibit agglutination has not been excluded.

Applications of agglutination and agglutination inhibition reactions

Because of the ease of their performance and high sensitivity, specific agglutination reactions have been employed for: 1) the serological diagnosis of infectious diseases through the detection of a rising titer (concentration) of serum antibody; 2) screening for specific tissue-directed antibodies in connective tissue and autoimmune diseases; 3) detection of the presence of antigenic determinants on cells (mixed agglutination reaction); 4) blood typing and cross-matching procedures for blood transfusion, including the use of antiglobulin as a second antibody to directly cross-link incomplete agglutinins bound to Rh and ABO blood cell antigens; 5) diagnosis of viral infection: influenza, rubella and other viruses that directly agglutinate erythrocytes. The inhibition of viral hemagglutination by specific antibody to the virus is a particularly useful and sensitive test for titers of antiviral antibody.

A number of lectins are employed in blood banks for the hemagglutination of erythrocytes through binding to A, B and H blood group substances, thus providing an alternative method of identification of blood group substances.

Quantitation

The agglutination method has fallen somewhat into disuse for research and, to some extent, even for diagnosis because it is not possible to precisely quantitate the reaction. Concentrations of agglutinating antibody are assayed by preparing a series of doubling dilutions of the test serum, adding cells to each dilution, incubating the cell suspension, and then observing the highest dilution of the serum which produces a visual agglutination pattern at the bottom of the tube. Thus, failure to observe the presence or absence of agglutination in one tube or one doubling dilution represents a 100% error in determining the quantity of antibody. Therefore, agglutination has been replaced by more quantifiable assays, including the ELISA, various radioimmunoassays and other types of immunoassays. However, agglutination can be quantitated. The actual amount of antibody nitrogen or protein bound by cells can be determined, but is too complicated and time-consuming to be a rou-

tine assay. Modern technology has provided a number of methods for the quantitation of agglutination through measurements of turbidity, light scattering or the mean diffusion constants of the particulate suspension.

Automated reading and processing of agglutination results

Microplate agglutination techniques are commonly used for the quantitative or qualitative isotypic analysis of specific antibodies, but require optical reading by the researcher and, therefore, can be quite subjective. Aubert and colleagues have used an automatic reader scanning each of the wells of a standard microtiter plate. The advantages of the automatic reader were additionally maximized by coupling it to a dedicated computer running customized software designed to process data coming on-line from the spectrophotometer. This approach was applied to the diagnosis of human toxoplasmosis and candidiasis. Suspensions of *Toxoplasma gondii* tachyzoites or of sensitized erythrocytes were used for the determination of IgG antibodies or the quantitation of IgM-, IgA- or IgE-specific isotypes.

Rapid agglutination testing in an ultrasonic standing wave

The time required to perform diagnostic agglutination tests can be significantly reduced by applying an ultrasonic standing wave field to a droplet of reagents in a capillary tube. Avian erythrocytes, bacteria and latex particles were agglutinated in 15 s, 5 min and 1 min, respectively with no loss in sensitivity or specificity. Moreover, a series of five droplets in a single capillary can be tested in less than 4 min by drawing the capillary along the axis of the ultrasonic field of a ring transducer.

Agglutination as a protective mechanism in infections

Specific agglutination of bacteria by antibody *in vivo* is observed only with rather enormous numbers of bacteria. Therefore, this serologic reaction is presumably not very important in natural infections of the bloodstream where enormous numbers of bacteria are unusual. In a local lesion, however, where the number of bacteria may be high, it is possible that agglutination of bacteria by antibody may aid in localizing the infection as well as keeping the growing bacteria in a clump rather than disseminating.

AGING AND THE IMMUNE SYSTEM

Bernhard Cinader, Department of Clinical Biochemistry, University of Toronto, Toronto, Canada

Lifespan and hence the rate of aging is a component of the evolution of different species. The magnitude of lifespan affects programs for sexual maturation and subsequent decline of reproductive activity. Body size and metabolic activity are in turn correlated with capacity for repair; this has been demonstrated for excision repair after DNA damage induced by ultraviolet light. Since the capacity for repair is limited, damage will ultimately result in age-related decline of synthetic capacity. While the quantity of products and the propensity for cell division generally diminish as a function of advancing age, amino acid sequences of proteins and nucleotide sequences of DNA do not change with age.

Having referred to factors which may determine differences in age-related progression of different species, we shall turn to differences in aging which occur in different individuals of the same species. It is reasonable to assume that some or many of these result from the presence of multiallelic genes with products which differ in their capacity to overcome wear and tear. This is certainly the case for individual differences in onset of diseases caused by inborn errors of metabolism. The age of the onset of several genetic diseases is related to the functional competence of the molecule which is defective in a

given disease. The absence of a particular molecule crucial for a given function, or the synthesis of an incompetent molecule, results in an early onset of the disease; the disease onset may be delayed if the molecule retains some functional capacity (e.g. Duchenne Becker muscular dystrophy, Sandhoff disease).

Aging of the immune system involves changes in the capacity for self-renewal, in the relative preponderance of cell populations and in the quantity of immunoglobulin molecules of different isotypes and of different interleukins. We have relatively little definitive information on the exact nature of changes in the capacity for self-renewal of stem cells and of precursor cells. There appears to be an age-related decrease in the number of cells which synthesize terminal deoxynucleotidyl transferase (TdT) and are precursors of both T and B cells. However, it remains possible that the observed decrease does not depend on changes in the precursor cells themselves but is due to regulator cells: feeder cells from old mice cannot support the *in vitro* growth of TdT⁺ cells, while feeder layers from young animals can do so. In short it is possible that self-renewal decreases with age as a function of regulator cells rather than of precursor cells themselves.

Age-related changes in the quantity of molecules

may be controlled by feedback mechanisms. There is considerable polymorphism in the quantity of molecules produced in young individuals of different genetic backgrounds. The quantity produced by the youthful organism is in many cases directly correlated to the extent of subsequent decrease; this correlation has been referred to as 'economic correction'.

In the immune system the most striking age-related change occurs in the thymus, in which some cell populations decrease and others show a compensating increase up to late middle age when the total number of self-renewing thymus cells becomes drastically reduced. These central cellular changes cause marked age-related changes in various subpopulations of T cells, and particularly in different classes of suppressor and of helper cells.

Individual differences, i.e. the polymorphism of age-related changes, will be exemplified in terms of two classes of suppressor capacity, one affecting the humoral, the other cell-mediated immunity.

Suppressor capacity in the thymus, affecting humoral response, can be measured by reconstitution experiments, in which lethally irradiated mice are given lymphocytes of young donors, mixed with thymus cells from donors of different ages; the reconstituted mice are then immunized, and antibody is measured. In some strains of mice, thymus cells from young donors reduce the humoral response of the lymphocytes, while thymus cells from old donors increase it.

Changes in suppressor capacity for cell-mediated immunity can be measured by the ability of thymus cells to prevent lymphocytes to be sensitized by targets and to kill them.

Within the same strain the potency of the two classes of suppressor capacity, i.e. suppressor capacity for humoral immunity and suppressor capacity for cell-mediated immunity can change in opposite directions. The independence of aging of the two classes can also be seen when progression of age-related changes are modified by nutritional, hormonal or pharmacological interventions; these can affect aging of one class without affecting aging of the other. In general, it seems that age-related changes of the two classes vary as if they were controlled by two different genes.

We shall now turn to changes in T helper cells, in terms of interleukins. In mice of different strains, interleukin 1 (IL-1) and IL-2 decrease with age, though to different extents. In striking contrast, IL-3, IL-4, IL-6 and IL-10 increase up to a fairly advanced age. These contrasting changes in the direction of age-related alterations of different interleukins may be attributable to relative changes in the proportion of two sets of T helper cells, T_H1 and

T_H2 cells, the latter include memory cells. Thus, changes of interleukins may result from a lifelong accumulation of encounters with foreign macromolecules, and so reflect immunological experiences.

In summary, considerable age-related changes in suppressor cells occur to an extent which shows individual variation; different types of suppressor cells can change in opposite directions in the same individuals. Changes in helper cells are attributable to changes in the relative proportion of subpopulations and manifest themselves in age-related changes in the quantity of different interleukins. In some strains of inbred mice these changes can result in a decrease in humoral response. In other strains of mice a marked decrease in suppressor cells for the humoral response can result in autoimmune disease.

In the heterogeneous human population, there is an age-related increase in the proportion of individuals who show a decrease in the capacity to make a potent immune response and a greater tendency to make autoimmune responses. From the foregoing discussions on age-related changes in different strains of inbred mice, it is clear that both changes observed in human populations can be interpreted as resulting from the heterogeneity of the population i.e. from individual differences in genetic background; some individuals have a tendency to the changes which we have observed in the age-related patterns of certain inbred strains of mice. In this context, it is intriguing that certain interleukins seem to increase in each of the five inbred strains examined; the question arises whether these changes might be advantageous.

In fact, this is not necessarily the case. Immunity to leishmania can be reduced via IL-3 and IL-4, which impair the capacity of macrophages to kill intracellular organisms. IL-4 can directly inhibit the induction of cytotoxic T lymphocytes (CTL) and lymphokine activated killer (LAK) cells against virus-infected cells and tumors. It is possible, therefore, that increases in interleukins may reduce the ability of the immune system to deal effectively with some infections. However, this is not necessarily applicable to all infections, indeed some changes of old age can have adaptive advantages. This appears to be the case in age-related decreases of factors which affect growth of certain tumors. In one situation, age-related decrease in the growth of some tumors is attributed to age-related decrease in the production of angiogenic factors by T cells of aged animals.

In several strains of mice, NK cells have been found to increase to middle age and then to decrease. Similar observations have been made with respect to LAK cells, which show polymorphism in the quantity of these cells in young individuals and subsequent decreases that are proportional to the magnitude of

the youthful level, i.e. 'economic correction'. There is a diversity of findings concerning the aging of human NK cells. One group reports an age-related decrease; others find no change; yet others find an increase of NK function with aging, most often correlated with an increased number of NK cells. Thus it might appear as if NK cells of humans and mice age in a different manner. In fact, this difference may be due to the difficulty of analyzing the relation between a given parameter in old, middle-aged and young human populations, since individuals with certain genetic traits are eliminated before old and middle age, but are present in the young population.

Some age-related changes of B cells are a manifestation of change in T cells and the accumulation of memory. However, there is some evidence that B cells from old mice are specifically defective in their ability to progress from the G₀ phase into the S phase of the cell cycle.

Having examined aging in T, NK and B cells, it remains to summarize the reason for the increase in autoimmunity in aging human populations. In part this may be attributable to the loss of suppressor capacity as has been found in some strains of inbred mice. In part it may be due to accumulation of denatured proteins which is the consequence of the age-related decrease in proteolytic enzymes. These denatured proteins may cause a breakdown of the tolerance which exists for intact autologous molecules.

Age-related changes are clearly compartmentalized in terms of different types of T suppressor cells and in terms of different subsets of helper cells. There is also a difference in age-related changes in the mucosal system and in the peripheral immune system; the former appears to be much less subject to age-related changes than the latter. The quantity of NK cells in mice goes through a peak in middle age and then declines moderately. In humans, this decline has not been observed and selected groups of aged individuals appear to have high levels of NK activity. There may be a decline in the self-renewal capacity of some stem cells but it is not clearly established whether or not this is in fact the outcome of the effect of controlling cells which prevent proliferation.

ALLELIC EXCLUSION

Michael Reth, Max Planck Institute for Immunobiology, Freiburg, Germany

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

In agreement with the proposal of the 'clonal selection theory' by Burnet in 1959, Nossal and Mäkelä could show in 1961 that indeed each B cell produced many copies of only one type of antibody. Thus each B cell is restricted to one specific antibody. With the discovery of allotypes another restriction of B cells was shown. Allotypes are serological markers on heavy or light chain of immunoglobulin (Ig) which differ among genetically different strains of one species. Anti-allotypic antisera can be produced by immunizing strain A₁ with strain A₂ Ig. Using anti-allotypic sera, Pernis, Chiappino, Kelus and Gell, as well as Cebra, Colberg and Dray, showed in 1965 that in an (A₁ × A₂) F₁ animal B cells express either A₁ or A₂ but not both allotypes on their cell surface. Hence, B cells are restricted to express Ig chain of only one of their two alleles, a phenomenon which is called 'allelic exclusion'.

The allelic exclusion control ensures that each B cell expresses only one type of binding site because an antibody binding site is determined by the combination of a particular heavy and light chain. Figure 1A shows that a B cell with a defined binding specificity can be efficiently selected and activated by the corresponding antigen. If expression of the Ig alleles was not regulated each B cell would express several combinations of the two different heavy and light chains and thus express a variety of antigen

specificities (Figure 1B). Such unregulated B cells would not be able to mediate a specific immune response.

Allelic exclusion in the context of V gene assembly

Most cells of the vertebrate species have a diploid chromosomal organization and express both alleles of an active gene. The Ig genes are an exception to this rule because only one of their alleles is expressed as a functional product. This phenomenon is connected with another special feature of the Ig genes; namely, that the gene for the variable part of an Ig chain (V gene) is not encoded in the germ line but assembled from different gene segments during B cell development. The genes for the variable region of the heavy (H) and light (L) chain are assembled out of three (V_H, D and J_H) or two (V_L, J_L) germ-line gene segments, respectively. This assembly is mediated by two recombinase proteins, RAG-1 and RAG-2 which are only expressed in cells of the lymphoid lineage. The V gene segments are found in multiple different copies at the IgH and the two IgL gene loci (Igκ and Igλ). V Gene rearrangements occur in the developing B cell in an ordered fashion first at the IgH locus and only later at the Igκ locus. Before the segments are assembled into either a V_HDJ_H or a V_LJ_L complex

Figure 1 Allelic exclusion ensures expression of a single specificity of antigen-binding site on the surface of the B cell.

their ends are frequently modified by the removal and/or addition of nucleotides. These modifications increase the variability of the expressed V genes. However, they may also result into a nonfunctional V gene in which the V_H or V_L segments are not joined in the correct reading frame to the DJ_H complexes or to the J_L segments (out of frame join). When the first sequences of both IgH and Ig κ alleles of B cells became available it was noticed that in most cases only one allele carried a functional (in frame) V_HDJ_H or $V_\kappa J_\kappa$ complex. At the Ig κ locus the second allele either did not carry any V gene rearrangements (germ-line configuration) or had assembled a nonfunctional $V_\kappa J_\kappa$ complex. At the IgH locus the second allele carried either a DJ_H or a nonfunctional V_HDJ_H complex. In a first attempt to explain these data it was proposed that allelic exclusion was simply due to a high frequency of nonfunctional V gene rearrangements (stochastic model). This model assumed that a V gene rearrangement occurs only once per allele and that due to the low frequency of a productive V gene rearrangement most developing B cells have either no or only one functional V gene. The latter population would then

be selected by the immune system. However, in studies of Abelson murine leukemia virus-transformed pre-B cell lines it became clear that the V gene assembly is a very dynamic process which can occur repeatedly on one allele. This is due to the fact that V gene segments are present in multiple different copies at each Ig locus. Thus a nonfunctional $V_\kappa J_\kappa$ complex can be deleted and replaced by a functional $V_\kappa J_\kappa$ complex on the same allele simply by joining an upstream V_κ to a downstream J_κ segment. Similarly a nonfunctional V_HDJ_H allele can become productive by performing a V_H to V_HDJ_H join. Further studies with pre-B cell lines also showed that the frequency of a functional V gene rearrangement was not very low. In a developing pre-B cell line roughly 30% of the analyzed V gene rearrangements are productive. However, in this analysis no cell line was found with a productive V gene on both alleles.

These data support the regulated model of allelic exclusion as proposed by Alt and Baltimore in 1982. According to this model the products of a functional V gene rearrangement exercise a feedback control preventing any further V gene assembly at a particular Ig locus. Thus in pre-B cells V_H gene rearrange-

Figure 2 Transmembrane signals regulate antigen-receptor gene rearrangement.

ment occurs on one or both IgH alleles until a productive V_HDJ_H complex is formed and a μ chain is produced. The μ chain then generates a signal preventing any further V_H gene assembly on both IgH alleles. Specifically it is the membrane-bound form of the μ heavy chain which exerts this feed back control, preventing any further V_H gene assembly on the two IgH alleles. In the endoplasmic reticulum of the pre-B cell the μ heavy chain binds to the surrogate light chain proteins VpreB and $\lambda 5$ as well as to the Ig α /Ig β heterodimer, the signaling component of the B cell antigen receptor. Together these molecules compose the pre-B cell receptor which at the cell surface initiates the signal for the expansion of the pre B cell clone and the inhibition of further V_H to DJ_H rearrangement (Figure 2A). Pre-B and pro-B cells in mutant mice lacking μ heavy chain, $\lambda 5$ or Ig β expression do not show allelic exclusion of the IgH alleles, thus demonstrating the importance of the pre-B cell receptor in this control. How signals from the pre-B cell receptor stops further V_H gene rearrangement is not known at present; presumably the V_H segments are the target of this control as the J_H-C_H locus is already transcriptional active during pre-B cell development. During the expansion of the pre-B cell clone the RAG genes are switched off, but are re-expressed later on so that V_L to J_L rearrangements can occur. These rearrangements continue until a light chain is produced which can bind to the pre-existing μ heavy chain (Figure 2B). The subsequent expression of a B cell antigen receptor on the cell surface results in termination of further V_L to J_L rearrangements, thus establishing allelic exclusion of the IgL loci. Allelic exclusion occurs not only at the IgH and IgL loci but also at the TCR β chain locus. Similar to that which has been described above for the pre-B cells, the control of the TCR β chain locus is mediated via a pre-T cell receptor consisting of the CD3 complex, the TCR β chain, and the surrogate

TCR α chain pre-T α . In contrast to the IgL loci the TCR α chain locus does not show a tight allelic exclusion control; why this is so remains to be established.

ALLERGENS

Martin D Chapman, Asthma and Allergic Diseases Center, University of Virginia, Charlottesville, Virginia, USA

The modern history of 'allergens' dates back to 1873, when Charles Blackley showed that wind-borne pollen grains caused the symptoms of June hayfever and that aqueous pollen extracts caused immediate wheal and flare reactions when scratched into the skin of a hayfever sufferer (himself). At the turn of the century, the causative agents of this

'supersensitivity' reaction were defined as allergens (Von Pirquet) and this form of immunity was shown to be mediated by homocytotropic (or 'reaginic') antibody (Prausnitz and Kustner). These historic developments are summarized in Table 1. By the 1920s, it was known that inhalation of allergens derived from pollens, house dust and animals, or

ingestion of foods, was associated with the clinical symptoms of hayfever, asthma, atopic dermatitis or food allergy, and that these conditions affected 10–20% of the population. This was a 'golden era' of research on allergic disease and, indeed, the first edition of the *Journal of Immunology* contained an article by Robert Cooke, some 100 pages long, on the genetics of asthma, showing that the disease had strong hereditary links. The second golden era was in the 1960s, when the first allergens were purified from ragweed and rye grass pollen, histamine release assays were developed, and the landmark studies of the Ishizakas established that immediate hypersensitivity reactions were mediated by a new class of antibody, termed immunoglobulin E (IgE).

Inhalation of environmental allergens is the most common cause of IgE responses in humans and this feature distinguishes this class of antigens from other macromolecules or infectious agents which, with the exception of helminth parasites, do not usually cause IgE responses. There has been tremendous recent progress in research on allergens. Most important allergens from pollens, dust mite, animal danders, insects and foods (e.g. peanut, shrimp) have now been cloned and expressed as recombinant proteins. Amino acid sequence data derived from these studies have been used to establish the structure and biologic function of allergens, to identify the antigenic sites that are involved in IgE responses, and to investigate cellular mechanisms of inflammatory responses in asthma and atopic dermatitis. Recombinant allergens are being introduced for the diagnosis of allergic diseases and for developing therapeutic products. Allergens are one of the most well-defined groups of biomedically important proteins and we are now entering a new era in which the molecular basis of

the immune response to these proteins is becoming established.

Nomenclature and general properties

Atopic individuals become sensitized to allergens through exposure by inhalation (e.g. pollen grains, mite feces, animal danders, cockroach secretions, and fungal spores), by ingestion (e.g. milk, egg, peanut, fish), and by injection (e.g. insect venoms and parenterally administered drugs, such as penicillin). In general use, the term allergen can refer to these sources, to aqueous extracts prepared from the source materials, or to highly purified or cloned allergen proteins. The systematic nomenclature for purified allergens developed by the World Health Organization and International Union of Immunological Societies was revised in 1994. The nomenclature uses the taxonomic name of the source material and an Arabic numeral to describe the allergen, in the chronologic order of identification and purification. In the abbreviated form, the first three letters are used for the genus, followed by a single letter for the species. For example, ragweed antigen E (the first pollen to be purified) is *Ambrosia artemisiifolia* allergen 1, or Amb a 1. To be included in this nomenclature, newly described allergens have to have clearly defined molecular properties and to have demonstrable allergenic importance according to criteria established by the IUIS subcommittee on allergen nomenclature (Table 2). This committee reviews all proposals for inclusion of allergens in the nomenclature. The aim is to avoid redundancy and to ensure consistent use of allergen names in scientific and medical journals.

In most cases, multiple allergic proteins have been

purified from a given source. Thus more than ten different allergens have now been isolated or cloned from house dust mites or grass pollens. Usually, 80–90% of patients make IgE antibody responses to one or two proteins, e.g. mite allergens from *Dermatophagoides pteronyssinus*, Der p 1 and Der p 2, and these 'major' allergens are often used for immunologic and clinical studies. The prevalence of IgE antibodies to other 'minor' allergens is lower (<40%) and there is also evidence that a greater proportion of IgE is directed against the major allergens.

Allergens possess several characteristic features that appear to be important for immediate hypersensitivity reactions. They are usually low molecular weight proteins or glycoproteins (5–50 kDa) that are readily soluble and elute rapidly (within 1 min) from the allergen source, e.g. pollen grains or mite feces. These properties facilitate rapid penetration at mucosal surfaces, cross-linking of IgE antibodies on the mast cell surface, and mediator release to give immediate symptoms. Some allergens, such as penicillin and low molecular weight chemicals, act as haptens and require binding to a protein carrier (usually albumin) in order to elicit IgE responses. Other characteristic features of inhaled allergens are that allergic individuals become sensitized following exposure to extremely low doses of inhaled allergen, typically <1 µg of a single mite or pollen allergen per year, with no apparent adjuvant, on airborne particles of ~5–40 µm diameter. This form of

immunization appears to prime preferentially for IgE antibody production and may be important in generating T cell (T_H2) responses with cytokine profiles that are required for IgE production.

Molecular biology

Cloning and sequencing

By the mid-1980s a large number of allergens had been purified using biochemical techniques, but in general the yields were poor and, apart from physicochemical properties, the molecular structures of these proteins were poorly defined. With the advent of molecular cloning techniques, the primary structures of many allergens were rapidly established and, by screening cDNA expression libraries with IgE antibodies, new allergens were identified and sequenced. More than 100 allergen sequences are now listed in protein databanks (GENBANK) and a partial listing of major allergens is shown in Table 3.

The aim of cloning and sequencing is to obtain the primary structure of the allergen and to express the allergen in recombinant form. For many major allergens, N-terminal or internal amino acid sequences, and monospecific antibodies, were available to confirm the identity of cDNA clones. In some cases, e.g. cat allergen, Fel d 1 or *Aspergillus* allergen, Asp f 1, the nucleotide sequences were obtained by polymerase chain reaction (PCR) using primers derived from amino acid sequence. However, the usual approach has been to isolate mRNA from allergen source material (e.g. pollen grains, mite or cockroach bodies, fungal spores) and to use reverse transcriptase to generate double-stranded cDNA, which is then packaged into λgt11 or similar expression vectors. The cDNA libraries are screened with pooled IgE antibodies from 6–8 allergic patients, or with high titer monospecific polyclonal antibodies, to identify cDNA clones expressing allergen. Increasingly, allergens are being identified solely based on screening cDNA libraries and this approach has been very successful for allergens which were previously ill defined, e.g. fungi (*Alternaria*, *Aspergillus*, *Trichophyton*); foods (peanut, shrimp); and insects (cockroaches, fire ants, hornets).

Protein families and biologic function

Phylogenetically related species usually produce allergens that share significant amino acid sequence homology. For example, the group 1 allergens from *D. pteronyssinus* (Der p 1) and *D. farinae* (Der f 1) show 80% homology and the group 2 allergens from these mites show 88% homology. Allergens showing

Table 2 Allergens: criteria for inclusion in the WHO/IUIS nomenclature

1. The molecular and structural properties should be clearly and unambiguously defined, including:
 - Purification of the allergen protein to homogeneity
 - Determination of molecular weight, pI and carbohydrate composition
 - Determination of nucleotide and/or amino acid sequence
 - Production of monospecific or monoclonal antibodies to the allergen
2. The importance of the allergen in causing IgE responses should be defined by:
 - Comparing the prevalence of serum IgE antibodies in large population(s) of allergic patients. Ideally, at least 50 or more patients should be tested
 - Demonstrating biologic activity, e.g. by skin testing or histamine release assay
 - Investigating whether depletion of the allergen from an allergic extract (e.g. by immunoabsorption) reduces IgE binding activity
 - Demonstrating, where possible, that recombinant allergens have comparable IgE antibody-binding activity to the natural allergen

Table 3 Molecular properties of common allergens

Source	Allergen	Mol. wt (kDa)	Homology/function
Inhalants			
Indoor			
House dust mite (<i>Dermatophagoides pteronyssinus</i>)	Der p 1	25	Cysteine protease ^b
	Der p 2	14	Epididymal protein
	Der p 3	30	Serine protease
	Der p 5	14	Unknown
Cat (<i>Felis domesticus</i>)	Fel d 1	36	(Uteroglobulin)
Dog (<i>Canis familiaris</i>)	Can f 1	25	Calycin
Mouse (<i>Mus musculus</i>)	Mus m 1	21	Pheromone binding protein (calycin) ^b
Rat (<i>Rattus norvegicus</i>)	Rat n 1	21	Pheromone binding protein (calycin) ^b
Cockroach (<i>Blattella germanica</i>)	Bla g 2	36	Aspartic protease
	Bla g 4	21	Calycin
Outdoor			
Pollens – grasses:			
Rye (<i>Lolium perenne</i>)	Lol p 1	28	Unknown
Timothy (<i>Phleum pratense</i>)	Phl p 5	32	Unknown
Bermuda (<i>Cynodon dactylon</i>)	Cyn d 1	32	Unknown
Weeds			
Ragweed (<i>Artemisia artemisifolia</i>)	Amb a 1	38 ^a	Pectate lyase
	Amb a 5	5	Neurophysins ^b
Trees			
Birch (<i>Betula verucosa</i>)	Bet v 1	17	Pathogenesis-related protein
	Bet v 2	14	Profilin
Foods			
Milk	β-Lactoglobulin	36 ^a	Retinol-binding protein (calycin) ^b
Egg	Ovomucoid	29	Trypsin inhibitor
Codfish (<i>Gadus callarias</i>)	Gad c 1	12	Ca ²⁺ -binding protein (muscle parvalbumin)
Peanut (<i>Arachis hypogea</i>)	Ara h 1	63	Vicilin (seed-storage protein)
Venoms			
Bee (<i>Apis mellifera</i>)	Api m 1	19.5	Phospholipase A ₂
Wasp (<i>Polestes annularis</i>)	Pol a 5	23	Mammalian testis proteins
Hornet (<i>Vespa crabro</i>)	Ves c 5	23	Mammalian testis proteins
Fire ant (<i>Solenopsis invicta</i>)	Sol i 2	13	Unknown
Fungi			
<i>Aspergillus fumigatus</i>	Asp f 1	18	Cytotoxin (mitogillin)

Latex			
<i>Hevea brasiliensis</i>	Hev b 1	58	Elongation factor
	Hev b 5	16	Unknown – homologous to kiwi fruit Protein of unknown function

^aMost allergens have a single polypeptide chain; dimers are indicated.

^bAllergens of known three-dimensional structure are also indicated.

a high degree of structural homology are also found in grasses and trees (group 1, group 5, etc.). It is quite common for a single allergen to show sequence polymorphisms, and variants with limited amino acid substitutions are termed *isoforms*. In some cases, e.g. birch pollen allergen, Bet v 1, the isoforms may have altered IgE antibody-binding properties.

Sequence similarity searches have enabled the protein families to which allergens belong to be ascertained and their biologic function to be identified. The major tree pollen allergens (e.g. Bet v 1) are related to pathogenesis resistance proteins; many

mite allergens are proteolytic enzymes (cysteine and serine proteases, trypsin and chymotrypsin); and muscle proteins such as tropomyosin and troponin have been identified as allergens in mites, insects and shellfish (Table 3).

Recently, a new family of proteins has been identified that causes IgE antibody responses – ligand-binding proteins or calycins. These proteins bind small hydrophobic molecules such as pigments and pheromones. Calycins were first identified as a result of cloning cockroach allergens and the family also includes the major rodent urinary proteins, milk

allergen β -lactoglobulin, and dog, bovine and equine allergens. It has been postulated that because many allergens, particularly from dust mites, are proteolytic enzymes, that this facilitates penetration through mucosal surfaces and induction of IgE antibody responses. There is also evidence that Der p 1 may upregulate IgE synthesis through its ability to cleave CD23, the low affinity receptor for IgE. However, several clinically important allergens have no enzymatic activity and there are other allergens which show no sequence homology to known proteins and whose function is as yet unknown (e.g. mite group 5 allergens) (Table 3).

Expression and biologic activity of recombinant allergens

Traditional methods of allergy diagnosis and treatment have relied on the use of heterogeneous allergen extracts. The problems with these extracts are that the absolute potency is difficult to define and some patients give adverse reactions when the extracts are injected (during immunotherapy), which can be life threatening. While there has been significant progress in the standardization of allergen extracts; the use of purified recombinant allergens expressed in bacteria, yeast or insect cells offers the prospect of using defined proteins for both diagnosis and treatment. An increasing number of recombinant allergens have been produced and it is possible to investigate whether cocktails of 3–4 allergens would be suitable for clinical purposes. Typical vectors in which allergens have been expressed include pGEX and pET (in *Escherichia coli*); pSAY-1 and *Pichia pastoris* (yeast), and the baculovirus system, giving yields of 1–10 mg l⁻¹. The allergens can be obtained with a high degree of purity and, in many cases, have excellent immunoreactivity on skin testing and in serum IgE antibody assays. Several recombinant allergens from mite (Der p 2, Blo t 5, Der p 5), aspergillus (Asp f 1), cockroach (Bla g 4, Bla g 5) and grasses (Phl p 1, Phl p 5) have been shown to have good biologic activity on skin testing, and elicit positive wheal and flare reactions using picogram doses of protein.

Molecular modeling and tertiary structure

Recombinant allergens are essential for providing sufficient quantities of highly purified protein for structural studies. It is also possible to manipulate allergen sequences and to produce partial constructs for investigation of functional or immunologic activity. Using site-directed mutagenesis, it has been possible to generate site-specific variants of Der p 2 that have reduced binding for IgE antibodies. These experiments allow B cell epitopes to

be localized and can also be applied to investigate functional domains of the allergen, for example, the active sites of enzyme activity or the ligand-binding regions.

The homology between allergens and other protein families can be used to generate molecular models of the tertiary allergen structure. Two recent examples involve mite allergen Der p 1, whose structure has been modeled on the cysteine protease, papain, and cockroach allergen, Bla g 4, which has been modeled on other calycin structures for which X-ray crystal coordinates were known (Figure 1). The X-ray crystal structures of several allergens have been determined, including mouse and rat urinary proteins (Mus m 1 and Rat n 1), ragweed Amb a 5, and chironomid hemoglobin.

Immune response

Allergic individuals make IgG, IgA and IgE antibodies to allergens in both serum and nasal secretions. It is not uncommon to find asymptomatic individuals with positive skin tests and allergen-specific serum IgE antibody; however, most 'nonallergic' individuals do not make IgE antibody responses. The levels of IgG antibody in nonallergic individuals are usually lower than in allergic

Figure 1 Molecular modeling of the cockroach calycin allergen, Bla g 4. The α backbone structures for two models of Bla g 4 (designated bg12A-1 and bg12A-2) were modeled on the X-ray crystal coordinates for butterfly bilin-binding protein (BBP) and are compared with rat urinary protein allergen (RUP), for which the X-ray crystal structure has also been determined. The conserved amino acid residue spheres form motifs which define the ligand-binding proteins, or calycins. (See also color Plate 7.)

patients and there is also evidence to suggest that the affinity for these IgG antibodies is lower. In hayfever patients, IgE antibodies to pollen allergens can account for a significant proportion (>20%) of the total IgE. IgE antibody responses to food allergens develop within the first few months of life, whereas antibody responses to inhaled allergens develop over the first 2–3 years of infancy. IgG antibody levels rise (up to 50-fold) in patients being treated by immunotherapy using aqueous allergen extracts. A rise in IgG antibody correlates with clinical efficacy in patients with insect venom allergy, but is not significantly associated with clinical improvement with inhaled allergens.

Recent work has focused on the role of T cells in regulating allergen-specific IgE responses. Proliferative T cell responses can be demonstrated *in vitro* using peripheral blood from allergic patients, and T cell clones specific for mite, pollen and cat allergens have been obtained. Assessing T cell responses to allergens is difficult because many patients, even with high antibody levels, make weak or inconsistent T cell responses. For these reasons, studies have often focused on small numbers of highly selected patients and there are few large population studies. T cell clones derived from allergic individuals have a predominantly T_H2 phenotype and secrete interleukin 2 (IL-2), IL-4 and IL-5. T cell clones have also been obtained from nonallergic individuals and these are T_H1 cells secreting interferon γ (IFN γ). Epitope mapping studies with Der p 1, Der p 2, Fel d 1 and Bet v 1, and other allergens, suggest that most allergens have multiple T cell epitopes, which are not HLA restricted, i.e. 'promiscuous' epitopes. In some cases immunodominant T cell sites have been identified, e.g. two 27 amino acid peptides on Fel d 1, chain 1.

There is also good evidence that allergen-specific T cells have inflammatory effects *in vivo*. Patch tests with purified mite allergens result in the recruitment of basophils, eosinophils and mononuclear cells into the skin of atopic dermatitis and the production of eczematous lesions at 48 h. The frequency of allergen-reactive T cells in the skin of these lesions is higher than in the peripheral blood. Allergen challenge in the lung also results in recruitment of inflammatory cells and is thought to be in part T cell mediated.

Now that the amino acid sequences of many allergens are known, strategies are being developed for new forms of allergen immunotherapy involving T cell epitopes and specifically designed molecules which no longer bind IgE. The key advan-

tage of these approaches is that the peptides can be synthesized, and any alterations in allergen structure can be clearly defined. One approach has been to immunize cat allergic patients with two immunodominant T cell epitopes of Fel d 1, with the aim of occupying the T cell receptor binding site without delivering the costimulatory signals that are necessary for IgE production. The cat vaccine is now undergoing clinical trials and early results show clinical improvements in treated patients, particularly at high peptide doses. Another approach is to design allergen vaccines containing a cocktail of recombinant allergens or variants which have been modified by mutagenesis so that they have markedly reduced binding to IgE. The rationale here is to deliver a broad spectrum of T cell epitopes and to reduce the possibility for IgE mediated side-effects.

Clinical significance

Allergic diseases such as hayfever, asthma and atopic dermatitis affect 10–20% of the population. Asthma is the most common chronic disease of children in Western countries and the prevalence of the disease has been increasing. Over the past 5–10 years, the clinical significance of allergens in causing asthma has become firmly established and there is now overwhelming evidence that sensitization to allergens is the single most important risk factor for the development of asthma. Asthma management has relied heavily on the use of bronchodilator and anti-inflammatory drugs (inhaled or oral steroids). In addition, greater emphasis on the role of indoor allergens in causing the disease has focused attention on the need to reduce allergen exposure in houses. Measuring allergen exposure in houses using monoclonal antibody based ELISA tests has established levels at which patients become sensitized (typically exposures of 1–2 μg allergen per gram dust) and at which they are likely to develop asthma exacerbations (>10 $\mu\text{g g}^{-1}$). Allergen avoidance studies carried out at high altitude or in hospital rooms have shown that reducing allergen exposure to <1 $\mu\text{g g}^{-1}$ can reduce bronchial hyperreactivity and improve asthma symptoms. Studies are now being designed to assess whether allergen avoidance protocols can be developed for routine use and whether early allergen avoidance procedures (in the first 3 years of life) will reduce the prevalence of asthma.

ALLOANTIGENS

Dhirendra N Misra, Heinz W Kunz and Thomas J Gill III, Department of Pathology, University of Pittsburgh, Pittsburgh, Pennsylvania, USA

Molecules expressed on biologically active cells include structural components, enzymes, receptors, transport system molecules, viral proteins and accessory molecules. Many of them carry unique determinants that can elicit xenogeneic and/or allogeneic immune responses. Alloantigens play crucial roles in the body's defense mechanisms and are of importance in the clinic with respect to blood transfusion and tissue or organ transplantation. Recent advances in serological and molecular biological techniques and in X-ray crystallographic structural analysis have increased our ability to identify and characterize new cell surface antigens and to understand their structure and function.

Alloantigenic polymorphism can arise in several ways: first, sequence variation in structural genes (e.g. major histocompatibility complex (MHC) antigens, Rh blood group antigens); second, variation in the activity of enzymes involved in the synthesis of antigenic epitopes (e.g. ABH or Lewis blood group carbohydrate determinants); third, sequence variation in regulatory elements controlling the expression of structural genes (e.g. expressed versus null alleles as for H2-T antigens in the mouse).

Alloantigenic responses also can occur in several ways: 1) alloimmunization; 2) natural immunization (e.g. naturally occurring antibodies against ABH antigens); and 3) the maternal immune response against fetal antigens during pregnancy (e.g. antibodies against human MHC antigens). Some major alloantigenic systems are described in the following section and summarized in Table 1.

Major alloantigenic systems

Blood group antigens

Hundreds of blood group antigens have been identified by red blood cell serology. The well-known major blood group alloantigenic systems (ABO(H), Rh) are very important from a clinical standpoint. The minor blood group systems (e.g. Lewis, MNS, Lutheran, Kell, Duffy, Kidd, P, I) also are clinically significant, but less so. The Rh system is one of the most polymorphic antigen systems known, as it comprises at least 50 antigens, all of which are encoded by alleles at either of two loci, D or CcEe; the D antigens are the most immunogenic of all the red blood cell antigens. The MNS system is also highly

Table 1 Major alloantigenic systems with their basic functions and clinical significance1. *Blood group antigens*

Minor systems: Lewis, MNS, Lutheran, Kell, Duffy, Kidd

Functional and clinical significance: blood transfusion, tissue or organ transplantation, hemolytic diseases and inflammatory responses2. *Histocompatibility antigens*

A. Major Histocompatibility antigens (MHC)

(a) Classical

Class I: Human HLA-A, B, C

Mouse H2-K, D, L

Rat RT1.A, F, E

Class II: Human HLA-DP, DQ, DR

Mouse H2-A, E

Rat RT1.H, B, D

Functional and clinical significance: presentation of antigenic peptides to T cells; association with susceptibility to a number of diseases; tissue and organ transplantation

(b) Nonclassical:

Class I: Human HLA-E, F, G, H, J, K, L; MIC (MHC class I chain related)

Mouse H2-Q, T, M

Rat RT1.C, K, G, O, N, M

Class II: Human HLA-DMA, DMB

Mouse Ma, Mb₁, Mb₂*Functional and clinical significance:* presentation of specific antigenic peptides to T cells; DMA/DMB act as accessory molecules in antigen presentation by class II antigens.

(c) MHC class III antigens

Human: C2, factor B (Bf), C4A and C4B (complement proteins); TNF α , TNF β (tumor necrosis factors); steroid 21-hydroxylase (CYP21); major 70 kDa stress protein Hsp70; and TAP (transporter of antigenic peptides)Mouse C2, C4, Bf, Slp (sex-limited protein), 21-hydroxylase (21-OH), Hsp70 and TNF α , TNF β Rat C2, C4, Bf, Hsp70, Cyp21, TAP, TNF α *Functional and clinical significance:* complement functions; transport of antigenic peptides; chaperones in antigen processing and presentation

(d) MHC-like antigens encoded by genes residing outside the MHC

Class I-like

Human, mouse, rat: FcRn

Human, mouse, rat: CD1

Human: Zinc α_2 -glycoprotein (ZAG)*Functional and clinical significance:* FcRn binds IgG from ingested milk from mother and transfers it across intestinal cells to the bloodstream; CD1 predominantly presents nonpeptide lipid and glycolipid antigens to T cells; and ZAG has no known physiological function

B. Minor histocompatibility antigens

(a) Sex-specific: H-Y (mouse, rat, human)

(b) Many tissue-specific antigens in all species

(c) Mls endogenous superantigens

Mouse: Mls-1^a, Mls-2^a, Mls-3^a*Functional and clinical significance:* slow tissue rejection, mixed lymphocyte stimulation

3. Differentiation antigens (CD)

In excess of 100 clusters have been identified in humans

Functional and clinical significance: Involved in cellular interactions.

complex, comprising two closely linked homologous genes GYPA and GYPB, that encode for at least 38 antigens. Recent studies at the molecular level indicate that a variety of genetic mechanisms gives rise to this complexity. So far, Rh antigens have been detected only on red blood cells, but the ABO(H), Lewis, P and I antigens are widely distributed throughout the body. Recent data suggest functional roles for blood group antigens unrelated to erythrocytes: cell adhesion, association with diseases, tumor

markers and receptors for parasites, bacteria and viruses.

Major histocompatibility complex antigens

There is extensive allelism of genes within the MHC; their numbers vary from a few in the miniature swine to hundreds in the African pigmy mouse. The MHC-encoded classical class I (class Ia) and class II molecules bind peptides derived from endogenous or exogenous self proteins as well as nonself proteins

from viruses, bacteria, multicellular parasite and many types of tumors. They present these peptides to mature CD8⁺ and CD4⁺ subsets of $\alpha\beta$ T cells, respectively, for subsequent generation of specific cytotoxic/suppressor or helper/inducer T cells. Within a population, the classical MHC molecules are highly polymorphic: for example, in the human, at least 20 HLA-A, 45 HLA-B and 14 HLA-C class I antigens are known to date. A similar degree of polymorphism exists for class II antigens.

Besides the classical MHC genes, there are a large number of MHC genes with limited polymorphism and restricted tissue distribution of their products. The nonclassical antigens (class Ib) RT1.K and HLA-G are the only MHC antigens expressed, respectively, in rat and human placental trophoblasts. In the mouse, the Qa-2 molecules are restriction elements for a wide variety of nonameric peptides with restrictive binding motif. For example, Qa-1 binds peptides derived from heat shock proteins. Some H2-T antigens present peptides to $\gamma\delta$ T cells, and the H2-M3 antigen presents peptides from intracellular pathogens such as *Listeria monocytogenes* and from allelic variants of a mitochondrial enzyme specifically containing N-formylated methionine, a unique structural component of prokaryotic mitochondrial proteins.

Recently, a second MHC class I-related oligomorphic gene family, MIC, has been detected in the human (near HLA-B), goat, pig, dog and hamster. This family appears to have evolved independently from other class I genes, since its gene sequences are quite divergent. No functions are known but their structure suggests antigen presenting capability.

There are also class I-like molecules encoded by genes residing outside the MHC and on different chromosomes. 1) Neonatal Fc receptor (FcRn) first detected in rats and more recently in mice and humans, is involved in the acquisition of passive humoral immunity in young mammals during the first few weeks after birth. FcRn binds immunoglobulin G (IgG) from ingested mother's milk and transports it through gut epithelial cells into the bloodstream by transcytosis. 2) CD1 is a small multigene family, so far detected in several mammals including the mouse, rat and human. These antigens do not show significant polymorphism. CD1 proteins present nonpeptide lipid (mycolic acid) or glycolipid antigens from intracellular mycobacteria such as *Mycobacterium leprae* and *M. tuberculosis* to CD8⁺ $\alpha\beta$ T, CD4⁺CD8⁺ $\alpha\beta$ T or $\gamma\delta$ T cells or T cells within epithelial sheets. 3) Zinc α_2 -glycoprotein, a zinc-precipitable protein of human plasma, is another oligomorphic MHC-unlinked

class I protein. No physiological role for this protein is known.

Unlike the nonclassical class I MHC genes, only a few nonclassical class II MHC genes have been reported. Human HLA-DMA and HLA-DMB and the murine homologs Ma, Mb₁ and Mb₂ are examples. The human genes encode a heterodimer, DMA/DMB, which is not a cell surface molecule but is associated with class II antigens in the endosomal compartment. There is evidence that it helps peptide presentation by conventional class II molecules.

Minor histocompatibility antigens

A large number of minor histocompatibility antigens which contribute to the slow rejection of grafts has been detected. For example, the sex-specific antigen H-Y in males may cause rejection of male organs or bone marrow grafts by MHC-identical female recipients. The epitope of the H-Y antigen has been mapped to an 11-residue peptide located near one end of the protein encoded by the conserved Y-chromosome gene SMCY, which is homologous to the SMCX gene on the X chromosome. Identical results have been reported for the mouse H-Y antigen.

Mls and superantigens

Mls, or minor lymphocyte-stimulating, antigens represent another class of alloantigens that are recognized by T cells *in vitro*. They are encoded by endogenous mouse mammary tumor virus genes (Mls-1^a, Mls-2^a and Mls-3^a) and they elicit a strong primary mixed lymphocyte reaction (MLR) between cells derived from mice sharing the same MHC haplotype. Subsequently, similar antigens, known as superantigens (SAGs), have been found which include exogenous products of gram-positive bacteria (toxins), retroviruses and mycoplasma. These antigens are presented to CD4⁺ T cells by class II molecules in association not with the peptide-binding groove but with an external face.

Immunoglobulin allotypes

Allotypic variants of immunoglobulin light chains and heavy chains exist in different species, and they arise due to allelic variation in the constant region genes. In humans, for example, the IgE isotype has two alleles, and the IgG3 isotype has as many as 14 alleles. Allotypes are useful in population studies, paternity testing and forensic science. Variation in the expression of certain allotypes may be related to disease susceptibilities. For example, the IgG2 isotype is associated with immune responses to certain

bacteria, and lack of the Km1 or G2m(n) allotypes increases the risk of *Haemophilus influenzae* and *Meningococcus C* infections. Disease susceptibility due to interactive effects between Gm allotypes and HLA antigens has also been reported

Differentiation antigens

Leukocyte differentiation antigens provide markers for different lymphoid cell types, define cell lineages and mediate crucial leukocyte-specific functions. From serological, biochemical, structural and functional homologies, many of the antigens have been grouped into clusters of differentiation (CD), and some CD genes are polymorphic or oligomorphic, while others are monomorphic.

The CD antigen clusters are involved in numerous functions. Some examples are given below.

Accessory functions:

1. Interaction with MHC antigens leading to T cell activation: CD3 associates with $\alpha\beta$ TCR on CD4⁺ and CD8⁺ T cells, and the complex binds to MHC antigens along with antigenic peptides.
2. Activation of T cells requires a second signal that is delivered by the interaction of CD80(B-7)/CD28 and B cells via CD40/CD40-ligand molecules.
3. Signal transduction: Thy 1 (CDw90) is a signal transduction molecule that plays a role in T cell activation through the TCR/CD3 complex. CD19 and CD21 are involved in signal transduction in B cell activation.
4. Cell adhesion (integrins and their ligands): involves cell-cell or cell-tissue interactions during microbial infections, inflammation, tumor formation, metastasis and neural development. For example, the antigen-presenting cells (APC) and CD4⁺ T cells are brought into close contact by interaction between LFA-1(CD11a/CD18) antigen on the T cells with its ligands ICAM-1 and ICAM-2 on the APC and also by interaction between LFA-3 (CD58) and its counterpart CD2 on the T cells.

Markers for different cell types: T cells (CD3), MHC class II-restricted T cells (CD4), MHC class I-restricted T cells (CD8), activated T and B cells (CD95), B cell lineage (CD19, CD20) and granulocytes (CD66).

Receptors for soluble molecules: Interleukins (CD25, CD121 through CDw130); Fc portion of IgG (CD16: Fc γ RIII; CD32: Fc γ RII; CD64: Fc γ RI) or IgE (CD23) and complement C3d (CD21).

Viral receptors: Human immunodeficiency virus (CD4); and Epstein-Barr virus (CD21 on B cells).

Enzymatic activity: CD10, CD13, CD26 (dipeptidylpeptidase IV); CD45 (phosphotyrosine phosphatase) and CD73 (ecto-5'nucleotidase).

Ion channels: CD20 forms ion channels and functions during receptor-mediated events.

Disease associations and clinical use: A few examples: defective CD43 expression on T cells with X-chromosome-linked Wiskott-Aldrich syndrome; some minor GPI (glycosyl-phosphatidylinositol)-anchored antigens (e.g. CD55, CD58, CD59) are deficient on the red blood cells from patients with paroxysmal nocturnal hemoglobinuria (PNH). Anti-CD19 antibodies are used to treat leukemias and lymphoma and anti-CD3 antibodies to treat renal, hepatic and cardiac allograft rejection.

Biochemistry and molecular biology of alloantigens

The majority of alloantigens are glycoproteins (e.g. MHC, MNS antigens), and the others are sialoglycoproteins (e.g. CD43), oligosaccharides (ABO(H), Secretor, Lewis, Li and P), sialo-oligosaccharides (sialyl-Lewis^x or sialyl-Lewis^a) or proteins (Rh). Most cell surface protein antigens are anchored through transmembrane hydrophobic interactions, but there is an increasing number of structurally diverse cell surface antigens that are anchored by a covalent linkage through GPI: Thy-1 (CDw90), Ly-6, Qa-2, RT6, CD14, CD55, CD59, CD73. Some antigens (CD58 (LFA-3) and probably CD55) occur in two forms: one has a GPI anchor, and the other has a transmembrane anchor. The GPI-anchored proteins are active in transmembrane signaling; for example, the GPI anchor of Qa-2 is essential for T cell activation via this molecule. In addition, a large number of alloantigens belong to the immunoglobulin supergene family: for example, membrane-proximal domains of MHC polypeptides, CD1, CD2, CD3, CD4, CD7, CD8, Ly-6, Qa-2, RT6, CD19, CD22, CD56, CD58(LFA-3), CD59 and CDw90 (Thy 1).

Molecular cloning and sequencing of many allo-antigen genes have revealed the basis of their polymorphism and provided some insight into their function, either directly or by analogy with sequences of previously known genes. Many of the blood group antigens have been expressed by transfection of cDNA into nonerythroid or nonhuman mammalian cells in order to study their functions. Also, recent

X-ray crystallography of a number of peptide-MHC antigen complexes and protein modeling have yielded detailed information about the structure-function relationships of the MHC antigens.

ALLOTYPES, IMMUNOGLOBULIN

Royston Jefferis, Department of Immunology, The Medical School, University of Birmingham, Birmingham, UK

Allelism is the existence of two or more variants of a given gene in an outbred population. Allelism within the immune system was first recognized for genes encoding immunoglobulin (Ig) molecules, through the antigenic properties of their protein products, i.e. antibody molecules. The extent of allelism at the Ig loci has resulted in the application of Ig phenotyping to paternity testing, forensic science, bone marrow transplantation, etc. Allelism and allotypy may be evident in its most diverse form within the major histocompatibility loci, where the phenotype of an individual may constitute immunological self-identity.

Nomenclature

In 1976 the World Health Organization (WHO) sponsored an expert committee meeting at which the nomenclature for human immunoglobulin allotypes

was systematized and a logical numerical system was proposed to replace the apparently illogical alphameric system that had evolved. However, many expert laboratories continue to use the alphameric system since reference can be made to original publications in which the allotypes were defined. Both systems may therefore be encountered in current literature. The allotype of an Ig molecule is recognized by the expression of a unique epitope (allotope) and is designated by a capital letter representing the heavy-chain isotype or light-chain type with a small m standing for marker, viz: Gm, Am, Em, Km. Further, where appropriate the subclass of the protein is shown by the inclusion of the appropriate numeral. Thus, G1m(f) refers to genetic marker or allotope f expressed on molecules of the IgG1 subclass; G2m(n) to allotope n expressed on molecules of subclass IgG2, etc. The human Ig allotypes currently recognized are summarized in Table 1 and those of mouse

Table 1 Human immunoglobulin allotypes

Isotype/type	Heavy chains						Light chain
	IgG1	IgG2	IgG3	IgG4	IgA	IgE	κ
Allotypes	G1m	G2m	G3m	G4m	A2m	Em	Km(Inv)

			v(27)				

NB: Numeric notation given within brackets.

and rabbit in Table 2. The genes encoding the allotypic products are identified using the italicized form of the epitope nomenclature and the alphameric or numeric identity as a superscript, e.g. *G1m^a*, *Km¹*, etc.

Serological reagents that identify the products of some allelic genes may not be available, presumably because the resultant protein structure is not immunogenic, in humans. An example is IgG2 proteins for which reagents are available that identify a G2m(n) allotype and allow IgG2 paraproteins to be

designated G2m(n⁺) or G2m(n⁻); a reagent is not available that specifically recognizes G2m(n⁻) molecules.

Some reagents define isoallotypic epitopes; these epitopes are expressed on the product of a gene that is allelic for a given Ig subclass but are also expressed on the products of the other subclass genes. An example is a reagent recognizing the nG1m(a) epitope; IgG1 proteins that are the product of the *G1m^a* gene express the G1m(a) allotope whilst proteins that are products of the allelic gene express the non-G1m(a) or nG1m(a) epitope. However, proteins of the IgG2 and IgG3 isotype also express the nG1m(a) epitope. Such reagents allow the typing of homogeneous proteins, but cannot be applied to polyclonal IgG or whole serum analysis.

Table 2 Mouse and rabbit immunoglobulin allotypes

Isotype/type	Allotypes
<i>Mouse</i>	
κ	None identified
λ	None identified
<i>Heavy</i>	
G1	4 ^{a,c,d,e,f,g,h} , 4 ^b
G2a	1 ^a , 1 ^b , 1 ^c , 1 ^d , 1 ^e , 1 ^f , 1 ^g , 1 ^h
G2b	3 ^{a,c,h} , 3 ^b , 3 ^d , 3 ^e , 3 ^f , 3 ^g
G3	None identified
A	2 ^{a,h} , 2 ^b , 2 ^{c,g} , 2 ^{d,e} , 2 ^f

C _{μ}	f71, f72, f73
C _{ϵ}	g74, g75
C _{γ}	d11, d12 e14, e15

Haplotypes

All the allotypes presented in Table 1 are expressed on immunoglobulin constant regions. Since the genes encoding the constant region of the heavy chains are closely linked within the IgG gene locus they are inherited together as haplotypes with a very low frequency of cross-overs. However, cross-over events have occurred during evolution, resulting in present populations expressing characteristic haplotypes, hence the usefulness of the allotype system in population studies. Thus in northern Europe (The Netherlands) the haplotype *G1m^f*; *G2mⁿ*; *G3m^b* is present with a frequency of 0.45 and virtually all individuals are homozygous for the *A2m¹* allele, however, amongst Nigerian Africans the *G1m^a*; *G2mⁿ*; *G3m^b* haplotype occurs with a frequency of 0.678 (the *G1m^f*; *G2mⁿ*; *G3m^b* haplotype not being encountered) and the *A2m²* allele with a frequency of 0.826.

The structural difference between alleles is frequently restricted to a single base change within a codon resulting in a conservative amino acid inter-

change; examples are lysine or arginine at residue 214 in IgG1 proteins correlating with the expression of G1m(z) and G1m(f) allotypes respectively and leucine or valine within κ light chains with the expression of the Km1,2 or Km3 allotypes. Similar minor structural differences are observed between allotypic variants of Ig constant region in the mouse, rat and rabbit.

Applications

The value of allotypes in population studies, paternity testing and forensic science will be apparent from the heterogeneity of haplotypes present within and between population groups (Table 3). The value in forensic science is emphasized by the sensitivity of assay systems and the stable expression of allotypes by immunoglobulin present in aged, dried blood samples. A more recent application is in bone marrow transplantation where allotype disparities between the donor and recipient allow monitoring of the success of the transplantation protocol. Postoperative expression of donor allotypes, not expressed by the recipient B cells, is indicative of successful grafting. Allotype matching of human (humanized) monoclonal antibodies to recipients of *in vivo* immunotherapy may be important in minimizing immunogenicity and anti-idiotypic responses.

Disease associations

Immunoglobulin levels may also be associated with allotype and several studies have established that individuals homozygous for G2m(n) have higher IgG2 subclass levels than those homozygous for G2m(n⁻), heterozygotes having intermediate levels. Since protective immune responses to certain bacterial species are restricted to the IgG2 isotype, these

findings may have implications for disease susceptibility. Such an effect has been reported for post-immunization levels of antibody to *Haemophilus influenzae* and *Meningococcus C* polysaccharides with individuals lacking the Km1 and G2m(n) allotype having an increased risk of infection. A more established finding is an interactive effect between Gm allotypes and HLA antigens on disease susceptibility. There is some evidence that antibody molecules of the same isotype but differing allotype may differ in their potential to activate effector mechanisms.

Detection

Although allotypes may be detected by a relatively simple hemagglutination system, it does employ a range of reagents that are only available from specialist hematology institutions such as national blood banking centers. Anti-allotype reagents are generally alloantibodies produced by apparently healthy blood donors and are induced to paternal allotype in multiparous women or to nonself allotypes in individuals receiving transfusions or undergoing deliberate immunization. The sample under review is assayed for inhibition of agglutination of human red blood cells coated with anti-Rh antibody of the appropriate allotype. Limited availability of these reagents has resulted in the development of some polyclonal reagents in heterologous species, but this is a generally difficult and unsatisfactory procedure.

The development of monoclonal antibodies has made assay systems widely available and allow new studies to confirm and extend the influence of Ig allotype on immune responsiveness. Generally, these reagents show preferential reactivity with the target allotope, rather than exclusive specificity. They must be used with care in assay protocols defined by the originating laboratory.

AMEBIASIS

John P Ackers, Department of Medical Parasitology, London School of Hygiene and Tropical Medicine, London, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The World Health Organization definition of amebiasis describes it as 'infection with *Entamoeba histolytica*, with or without clinical symptoms'. It has long been known that at least 90% of patients with amebiasis will be asymptomatic cyst passers but only recently appreciated that these cases are caused by a separate species of ameba, now usually referred to as *Entamoeba dispar*; it is generally felt that about 450 million people carry this organism without either pathology or an immune response. At least 50 million new cases of infection with *E. histolytica sensu stricto* are thought to occur each year; the proportion of those infected who show clinical symptoms at any one time is hotly debated but everyone agrees that all are at risk. The remainder of this entry will deal exclusively with *E. histolytica* in its new sense – previously described as the 'pathogenic zymodeme'. Methods of distinguishing it from *E. dispar* (they are morphologically identical) are only slowly coming into use and this must be borne in mind when reading any but the most recent literature.

Characteristics of the organism and its antigens

E. histolytica is a protozoan parasite that lives in the large bowel (probably mostly adhering to the mucosa) as an ameboid and phagocytic trophozoite dividing by binary fission. Responding to unknown stimuli, trophozoites may develop into resistant cysts which are shed in the feces and, by being ingested orally, are responsible for parasite transmission. Pathology occurs when trophozoites penetrate the mucosa causing ulceration and bloody diarrhea (amebic dysentery, AD); less frequently dissemination to the liver takes place with, ultimately, extensive tissue destruction (hepatic amebiasis or amebic liver abscess, ALA). ALA is about seven times less

common than AD, and dissemination to other sites (brain, skin, etc.) is rarer still, but together these conditions cause much morbidity and 40–100 000 deaths a year, mainly in developing countries. Dissemination is aided by a formidable array of cytotoxic and cytolytic activities, most of which seem to have homologs in *E. dispar*; the specific factors which account for the invasive potential of *E. histolytica* have not yet been identified.

Western blots probed with patients' sera reveal a large number of immunogenic molecules, of which the best characterized are: the galactose/N-acetyl-D-galactosamine inhibitable lectin (GIL), a 260 kDa heterodimeric molecule involved in binding to and killing enterocytes; SREHP, a phosphorylated and glycosylated serine-rich membrane protein; a 29 kDa cysteine-rich protein (CRP) which may be involved in protection against oxygen toxicity; a 125 kDa variable surface antigen; additional 112 and 220 kDa molecules also capable of mediating adhesion; and a number of proteases.

Immune responses of the host

Antibody

Using sensitive tests, specific serum antibody may be detected in virtually all persons infected with *E. histolytica*, whether they have symptoms or not, although levels are significantly higher in those with ALA. Principally immunoglobulin G (IgG), and to a lesser extent IgA, are represented; IgM declines fairly rapidly while specific IgG remains elevated for months or years, reducing the diagnostic value of serology in endemic areas. In one study levels of specific IgG4 >> IgG2 > IgG3 > IgG1 were found. Coproantibodies have been detected in the feces of AD patients, and specific secretory IgA in the saliva and colostrum of those with ALA. Autoantibodies

(directed against liver, colon, neutrophils and IgG) and circulating immune complexes have been described in patients but there is no real evidence for immunopathology in human amebiasis.

Cell-mediated responses

On histological examination neither the ulcers of AD nor the hepatic abscesses of ALA show much evidence of cellular infiltration and granuloma formation; one exception to this is the ameboma, a rarely found mass of granulation tissue in the colonic lumen. In small animal models intense inflammatory changes occur early in the development of lesions but whether this occurs in human amebiasis is not known. After recovery, most ALA patients are skin-test positive but appear to be specifically unresponsive to *E. histolytica* antigens earlier on.

Most studies have shown that normal human leukocytes of all sorts are harmless to and are killed by *E. histolytica* trophozoites. ALA patients' CD8⁺ cells became cytotoxic after incubation with soluble amebic antigen, phytohemagglutinin or GIL. More importantly, antigenic stimulation results in the production of cytokines (interferon γ (IFN γ) seems to be the most important) which activate macrophages to kill trophozoites. *E. histolytica* is powerfully chemotactic for neutrophils, which are rapidly killed by a contact-mediated, GIL-dependent process; lytic enzymes liberated from these dead cells may be responsible for much of the tissue destruction seen in amebiasis. IFN γ and tumor necrosis factor α (TNF α)-activated neutrophils can kill trophozoites and N-formylmethionine leucyl phenylalanine (fMLP)-activated eosinophils can do so even more effectively, although, again, normal cells are killed by contact with *E. histolytica*.

Role of complement

It seems inevitable that *E. histolytica* must reach the liver via the portal circulation and therefore obvious that it must survive the journey. Reed and her colleagues showed that while all *E. dispar* isolates (and old, laboratory-adapted *E. histolytica* isolates in axenic culture) were lysed, freshly isolated strains of *E. histolytica* in xenic culture were apparently largely resistant to complement activated by the alternative pathway. This fact alone could have been enough to explain the noninvasiveness of *E. dispar*. At least two resistance mechanisms have been postulated – cleavage of C3 by the parasite's own cysteine protease and one involving yet another function for GIL – the molecule shares sequence similarities and antigenic cross-

reactivity with the complement regulatory protein CD59 and inhibits *E. histolytica* lysis mediated by C5b-9. However, Hamelmann and coworkers have obtained quite different results – non-pathogenic isolates (i.e. *E. dispar*) were nearly unaffected; freshly isolated pathogenic strains (i.e. *E. histolytica*) were susceptible to lysis and became more so on long-term cultivation, with or without bacteria. Complement resistance could only be acquired by hamster liver passage or by growth in media containing increasing concentrations of normal human serum. The results of the two groups are incompatible and the differences need to be resolved before the role of complement in amebiasis can be assessed.

Animal models

There are currently no realistic small animal models of human amebiasis; in all cases trophozoites must be injected directly into cecum or liver. Mice, with the exception of SCID animals, are almost completely resistant and the large literature is concerned with the *in vitro* effects of murine macrophages. These cells (like their human counterparts) can be activated for killing by IFN γ and TNF α ; the process appears to be nitric oxide mediated and TNF α increases the expression of nitric oxide synthase. The preferred model of ALA involves intrahepatic challenge of gerbils or hamsters (see below, Vaccines) where treatments which suppress cell-mediated immunity seem to enhance abscess formation.

Evasion strategies by the organism

These obviously exist, since amebic liver abscesses can enlarge relentlessly in the presence of high levels of circulating antibody, but their nature is not fully understood. Surrounded by necrotic tissue the parasite may not be exposed to the full concentration of serum antibody, and that which does bind is capped and shed very rapidly. Host cell-mediated responses are probably delayed and blunted by a number of mechanisms: antigen processing cells and effector cells are often killed on contact with the parasite; a monocyte (but not polymorph) locomotion inhibitory factor is produced which will minimize infiltration; and patient serum contains a factor that suppresses the production of activating cytokines by T cells – this may be the same as the parasite T cell mitogen which has recently been identified with GIL. Animal experiments have shown that macrophages from gerbil liver abscesses are deficient in the generation of reactive oxygen species, unresponsive to lymphokines and not cytotoxic (cells treated with *E. histolytica* extract *in vitro* showed much the same defects) while parasite proteins suppress the IFN γ -

induced expression of major histocompatibility complex (MHC) class II molecules by murine macrophages. All this suggests that host immune responses need to be suppressed to permit long-term parasite survival and so it is surprising that, while the severity of amebiasis is markedly increased in pregnancy or by corticosteroid treatment, there is virtually no evidence for such a phenomenon in patients with the acquired immune deficiency syndrome.

Vaccines

Vaccine developers always like to see solid immunity following the natural infection, but only one study has produced evidence of this for ALA and there is none from AD patients. Considerable success has been achieved in protecting small animals against challenge, but the artificiality of the models (see above) should be remembered when assessing how close we are to a human vaccine. Gerbils have been protected against intrahepatic challenge by CRP, by GIL (as have rats) and a recombinant fragment thereof, and by recombinant SREHP; and SCID mice by passively transferred anti-SREHP. The same antigen administered orally with cholera toxin has produced high levels of sIgA in mice and primates (but these animals cannot be realistically challenged) and the SREHP gene has been expressed in a *Salmonella typhimurium* vaccine strain. Progress is being made but there is still a long way to go.

AMPHIBIAN IMMUNE SYSTEM

Jacques Charlemagne, Groupe d'Immunologie Comparée, Université Pierre et Marie Curie, Paris, France

Annick Tournier, Laboratoire d'Immunologie Comparée, Université de Bourgogne, Dijon, France

Living amphibians are the descendants of the first tetrapod vertebrates that diverged from their lungfish-like ancestors in the Devonian period, about 450 million years ago. Urodela (newts, salamanders), Anura (toads, frogs) and Gymnophiona (limbless coecilians) are the three orders of the Lissamphibia infraclass and they actually represent about 4000

species. From their key position in vertebrate evolution, amphibians are important models for the developmental and comparative analysis of the immune system. Two species are currently studied: the New World urodele *Ambystoma mexicanum* (axolotl, a neotenic species) and the African anuran *Xenopus laevis* (South African toad, or clawed toad).

Lymphoid organs and lymphocytes

The amphibian thymus anlagen arise from the dorsal epithelium of the second (anuran), or third, fourth and fifth (urodeles) pharyngeal pouches. In *Xenopus*, the thymus buds are rapidly colonized by hematopoietic precursors, and by day 6–8 the cortex–medulla architecture becomes visible. The larval thymus involutes during metamorphosis, but efficient regeneration occurs in the metamorphosed froglet. The thymus then regresses at the time of sexual maturity. In axolotl the thymic anlagen appear at the time of hatching, 3 weeks after fertilization. The thymus buds are invaded by hematopoietic precursors 12 days after hatching, and the thymus develops slowly up to sexual maturity (about 12 months), and then regresses. The urodele thymus shows no cortex–medulla differentiation. The axolotl and *Xenopus* thymus contains most of the cell types that constitute the stroma of mammalian thymus, such as macrophages, nurse-like cells, cortical large dendritic cells and different types of epithelial cells.

The spleen appears about 12–14 days following fertilization in *Xenopus* and the mature spleen has a clear-cut red and white pulp, but no structures reminiscent of the avian and mammalian germinal centers. The axolotl spleen anlagen appear at the time of hatching (about 3 weeks after fertilization). Although some red/white pulp-like organization can be seen macroscopically, there is no follicular-like structure and no germinal centers. In urodeles and anurans, the hematopoietic peripheral layer of the liver supports B cell lymphopoiesis and granulocytopoiesis.

Immunoglobulin M (IgM)-producing cells can be observed along the digestive tract in axolotl, and IgM-, IgX- but no IgY-producing cells are present in the digestive tract of *Xenopus*. The anuran kidneys contain B lymphocytes, and can retain antigens in the intertubular tissue. Amphibians possess B cells and T-like cells in the blood and in *Xenopus* these cells can collaborate *in vitro* in a major histocompatibility complex (MHC)-restricted manner for the production of antibodies to T cell dependent antigens.

B Cells can be recognized in axolotl and *Xenopus* by monoclonal antibodies (mAbs) specific for the different heavy (H) and light (L) Ig chain isotypes. More difficult was the production of mAbs specific for T cells. In the axolotl, mAb 34.38.6 labels all thymocytes, 60–63% of sIg⁺ splenic lymphocytes, hematopoietic stem cells, granulocytes and macrophages of normal animals, but only 9% of splenic lymphocytes from thymectomized animals. A polyclonal antibody (L12) coprecipitates several (38, 43 and 22 kDa)

covalently linked molecules that form a multimeric complex on the axolotl T cell surface.

A membrane glycoprotein (120 kDa), which may be a CD8 equivalent, has been identified on *Xenopus* J strain T cells using mAbs XT-1 and AM22 which recognize *Xenopus* cortical thymocytes and a subpopulation of peripheral T cells. mAb AM15 recognizes a 18 kDa protein on a subpopulation of *Xenopus* T cells. Two mAbs (anti-CTX: 1S9-2 and X71) stain a subpopulation (65–80%) of *Xenopus* cortical thymocytes which are also labeled by mAb AM22 (anti-CD8-like), and thus could be the *Xenopus* equivalent of the avian and mammalian cortical DP thymocytes.

In tadpoles and adult *Xenopus*, the use of classical mitogenic agents, such as lipopolysaccharide (LPS), phytohemagglutinin (PHA), concanavalin A (Con A) and purified protein derivative (PPD), stimulate *in vitro* proliferation of B cells and T cells with the same responses that are seen in mammals. The PHA and mixed leukocyte responses are sensitive to thymectomy. Furthermore, a T cell growth factor similar to interleukin 2 (IL-2) is produced by stimulated T lymphocytes.

The axolotl has a population of B lymphocytes that proliferate in the presence of LPS at all steps of ontogenesis. The splenic T cells from adult, but not from young axolotls, proliferate significantly in response to PHA and Con A. Axolotl lymphocytes are also stimulated *in vitro* by the enterotoxins A and B from *Staphylococcus aureus*.

Lymphocyte antigen-specific receptors

T cell receptors (TCRs)

No antibodies have yet been produced against TCR-equivalent molecules in amphibians and the present knowledge regarding these molecules comes from recombinant DNA studies. Genes encoding the α and β chains of the axolotl TCR have been cloned. Five V α and 14 J α segments have been identified, and the structure of the CDR α 3 loops is in good agreement with that of mammals. The C α domain has the typical structure of mammalian and avian C α s, including the charged residues in the transmembrane segment that are thought to interact with other proteins in the membrane.

Fourteen V β families have been identified in the axolotl and several V β are sequence-related to the human V β 13 and V β 20 segments and to their murine V β 8 and V β 14 homologs. Four C β isotypes have been detected, C β 1, C β 2 and C β 3 show a high degree of identity, but the C β 4 is divergent (43–48% identity with C β 1–3). The transmembrane axolotl C β domain maintains the lysine residue which is

thought to be involved in the charged interaction between the TCR $\alpha\beta$ heterodimer and the CD3 complex. Specific J β segments are associated with each C β isotype and 4 D β -like sequences have been identified, suggesting that the axolotl TCR β locus may be organized into at least four independent (D β -J β -C β) clusters that use the same collection of V β segments.

The V β segments in *Xenopus* are organized into nine independent families, each containing one, or a few, members. Eight J β segments and two D β core segments have been detected, with probably a single C β .

B cell receptors (BCRs)

Two high molecular weight (IgM and IgX) and one low molecular weight (IgY) Ig classes have been characterized in *Xenopus*. The three heavy (H) chain isotypes can associate with 25, 27 and 29 kDa light (L) chains but almost no C ν (IgY) chain is associated with the 27 kDa L chains.

The genes encoding *Xenopus* H μ , H ν and H χ chains and the three L chain (ρ , σ and type III- λ -like) isotypes have been recently cloned. The C μ region is well related to other vertebrate C μ , and the C ν region of the IgY molecule is structurally related to avian C ν and mammalian C ϵ . The C χ region is not clearly phylogenetically related to any other vertebrate isotype. Switch regions are found 5' to the C ν and C χ genes and a DNA switch recombination event leads to the expression of C χ . Eleven V H families, about 15 D H segments and 9 J H segments have been detected in the *Xenopus* IgH locus. The V, D and J elements can rearrange randomly, and junctional diversity arises at the V-D and D-J junctions, with the possible occurrence of random nucleotide deletion (nibbling) and template (P) or non-template (N) nucleotide addition.

The *Xenopus* L ρ chains are homologous to the mammalian L κ chains. One C ρ and five J ρ elements that rearrange randomly with several members of a single V ρ family have been detected. The L λ (also called type III) chains are built from at least six V λ families, two J λ and two C λ segments; this is the most diverse *Xenopus* L chain isotype. The L σ chains consist of two (C σ 1 and C σ 2) isotypes and two (V σ 1 and V σ 2) families that rearrange with their own set of J σ 1 and J σ 2 elements.

High molecular weight (IgM) and low molecular weight (IgY) Ig classes are present in the axolotl. No B cells double stain with anti- μ and anti- ν mAbs, suggesting that B μ and B ν cells might represent independent B cell lineages. The axolotl C μ and C ν are closely related to their *Xenopus* counterparts and additional cysteines in C ν 1 and C ν 2 domains are consistent with an additional intradomain S—S

bond similar to the avian C ν and the human C ϵ . Eleven V H families, six J H and two D H segments have been identified and the same collection of V H segments is used by IgM and IgY molecules. However, it is not known whether, as found in *Xenopus*, an IgM to IgY switch occurs in individual B cells.

Major histocompatibility complex (MHC)

The *Xenopus* MHC is a single genetic region encoding classical class Ia and class II molecules. A distinct chromosome harbors nine subfamilies of nonclassical class Ib genes. *Xenopus* has a single classical class Ia locus, and a single polymorphic class Ia molecule per MHC haplotype is expressed in all *Xenopus* species, regardless of the ploidy. They display three class II β genes, with a pattern of nucleotide substitutions in the β 1 distal domain essentially similar to that found in functional mammalian class II genes.

Classical class Ia genes have also been characterized in the axolotl and show a strong structural homology with *Xenopus* class Ia genes. However, axolotls display 10–12 class Ia genes detected by Southern blot. Class II genes are not yet characterized.

The tissue distribution of MHC class I and class II molecules in the adult amphibian is somewhat similar to that seen in mammals: class Ia are ubiquitously expressed in all tissues except brain and gonads and class II are expressed by B lymphocytes and T lymphocytes. Class I molecules are not expressed in *Xenopus* before metamorphosis, but can be detected as soon as hatching in the axolotl.

The *Xenopus* MHC genetic region encoding class I and class II molecules directs rapid graft rejection, mixed lymphocyte reaction (MLR) and T-B collaboration. T cells interact with antigen-presenting cells similarly to mammals, and the *in vitro* secondary proliferative response is MHC restricted.

Immunobiology of T and B cells

Thymectomy in *Xenopus* either decreases or abolishes allograft rejection, MLR, PHA responsiveness, IgY antibody synthesis and antibody responses to thymus-dependent antigens. It does not abolish *in vivo* or *in vitro* responses to thymus-independent antigens or B cell polyclonal activation (LPS). *In vitro* assays using purified T and B cells from carrier- or hapten-primed *Xenopus* of various MHC types indicate that T cell help is involved in the differentiation of thymus-dependent antigen-primed B cells and that T-B collaboration is MHC restricted. IgM is produced first following antigenic stimulation, and

then is produced in conjunction with IgY. A second injection generates a significantly stronger ($\times 10$ – 100), mainly IgY, secondary response. Although somatic mutation occurs in *Xenopus* V_H segments at almost the same frequency found in mammals, these mutations may not be properly selected, perhaps because of the absence of germinal centers in the lymphoid organs.

Larval thymectomy suppresses allograft rejection in urodeles, but does not abolish *in vivo* responses to certain thymus-dependent antigens, such as sheep or horse erythrocytes. Larval and adult thymectomy, low dose (50–150 rads; 0.5–1.5 Gy) irradiation and hydrocortisone treatment enhance specific antibody synthesis against erythrocyte antigens. These observations suggest that T cell help is impaired in urodeles, but that some kind of T cell-dependent suppression acts on antibody production. Urodeles can be immunized against particulate but not against soluble antigens, and in normal and thymectomized axolotls IgM is the single antigen-sensitive Ig class, specific IgY is not produced. The kinetics of the antibody response is slow and there is no occurrence of a typical secondary response following hyperimmunization. Thus, although the *Xenopus* and axolotl IgY molecules are clearly homologous at the molecular level, their respective physiological functions are different: IgY are IgG-like (thymus dependent, sensitive to thymectomy) in anurans, but IgA-like in axolotl, at least in the first 7–8 months of development; most IgY are found associated with the digestive epithelium and are secreted into the gut lumen following transepithelial transport in association with secretory component-like molecules.

Ontogeny of the immune response

Xenopus tadpoles develop allorecognition (graft rejection, MLR) from about 12 days after fertilization, but the capacity to reject or to tolerate grafts depends on genetic background (minor non-MHC, or MHC differences) and on the balance of several parameters, such as the size of the grafts, age of tadpoles and breeding conditions. Metamorphosis is a crucial period when a high frequency of allogeneic grafts can be tolerated and this seems to be an active phenomenon, as thymectomy before metamorphosis decreases the level of tolerance. MLR and the splenic response to T cell mitogens are depressed at metamorphosis, but recover in the young froglet. This might be correlated to the transient decline in the number of lymphocytes at the time of metamorphosis, and could be a means by which the metamorphosing tadpole is able to remain unreactive to the numerous new self antigens that appear during

the metamorphosis climax, and an opportunity for the young froglet to build a new repertoire of self tolerant T cells.

The anti-DNP antibody spectrotypes are different and less heterogeneous in *Xenopus* tadpoles compared with adults, suggesting that pre- and post-metamorphosed *Xenopus* express different antibody repertoires. B cells can first be detected in the liver at 3–4 days; a second wave of B cell production possibly arises after metamorphosis, accounting for the detection of two successive antibody repertoires. Sequential rearrangement of V_H genes occurs from day 5 in developing tadpoles, all the J_H and D_H elements are randomly expressed at early larval stages, and the production of specific antibodies arises at about 10 days. Most antibodies are IgM; switching to IgY seems not to be efficient before metamorphosis, although Igs of the three classes are present in tadpole serum.

Urodele development is much slower than anuran, and lymphoid organs begin to develop at the time of hatching, 2–3 weeks after fertilization. *Ambystoma tigrinum* (tiger salamander) larvae begin to reject allografts at about 40 days following fertilization and seem to be fully competent for rejection at 100 days. Thymectomy efficiently suppresses allograft rejection when performed at 50–60 days. Clusters of IgM- and IgY-producing B cells are first seen in the spleen of 70-day-old axolotls, 30 days after differentiation of the spleen anlagen. IgM is first detected in the serum at 90 days (4% of the adult value) and its concentration linearly increases until 13 months. IgY is first detected at 7 months (5% of the adult value) and its concentration increases rapidly until 11 months. However, abundant secretory IgY molecules are present in the stomach and intestinal mucosa of young axolotls from day 50, and until the 7th month. IgY then progressively disappears from the gut but becomes detectable in the serum.

Tumors of the immune system

Several spontaneous thymus lymphoid tumors have been detected in the *Xenopus* colony by Louis Du Pasquier at the Basel Institute for Immunology. The first one (MAR1) was from a 4-year-old *Xenopus* of the ff strain and was transplantable in isogenic ff tadpoles and froglets, but not in fully adult animals. *In vitro* cell lines were derived from MAR1 (e.g. B3B7). Three other tumors were found, one from the ff strain (ff-2), and two from the LG15 strain (LG15/0 and LG15/40). All these tumors are sIg⁺, and MHC class I molecules are not expressed on the surface of B3B7, 15/0 and 15/40, but are present (with β_2 -microglobulin) on the surface of ff-2

cells. All the lines are labeled by mAbs X21.2 (thymocytes), AM22 (CD8 equivalent), and B3B7, ff-2 and 15/40 express large quantities of the CTX antigen which is thought to be a marker of the cortical DP lymphocytes. In the B3B7 line, the two alleles of the IgH locus are rearranged in frame (but are not transcribed), the two alleles of the IgL ρ locus seem to be deleted, and the two alleles of the IgL σ locus are rearranged – one is out of frame and the second uses a V σ pseudogene. These *Xenopus* lymphoid cell lines resemble some rare types of mammalian leukaemia and represent very useful tools for the analysis of lymphoid cell differentiation and Ig and TCR gene expression.

AMYLOID

Alan S Cohen, Amyloid Program, Boston University School of Medicine, Boston, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Although a waxy tissue deposit was observed in pathologic laboratories in the early eighteenth century, it was Rudolph Virchow in 1854 who called these 'lardaceous deposits' of the liver and spleen amyloid, when he found them to stain with iodine and sulfuric acid. This belief that the material was made up of carbohydrates (i.e. cellulose) was challenged, and the proteinaceous nature of the substance was generally accepted by the turn of the century. Most amyloid was thought to be related to chronic infections (tuberculosis, osteomyelitis) and subsequently to chronic inflammation (rheumatoid arthritis) and the term secondary or reactive amyloid has persisted in the clinical literature. In 1886, it was noted that amyloid could appear *de novo* and the then unusual clinical form named primary or idiopathic amyloid was discovered. The association of amyloid with aging, especially in the brain and heart, was long known, but regarded as incidental epiphenomena until recent years. Finally in 1952, in Portugal, a hereditary amyloid polyneuropathy was described, and has led to a growing literature of multiple kinships of hereditary amyloid.

Definition

Amyloidosis is now regarded as a generalized deposit of the protein amyloid extracellularly throughout parenchymal tissue (liver, spleen, kidney, adrenal), blood vessels, and heart. Virtually any tissue or organ may be involved, and in some cases the deposition is localized to a single area. The amyloid itself is an eosinophilic hyalin material, which after Congo red staining demonstrates green birefringence on polarization microscopy. Electron microscopy has shown amyloid to have a fibrillar ultrastructure and by X-ray diffraction it has a classical cross- β (β pleated sheet) appearance. It has generally been classified clinically as 1) Secondary (reactive) amyloidosis; 2) primary (idiopathic) amyloidosis; 3) amyloid associated with multiple myeloma (now known to have the same chemical characteristics as primary amyloid); 4) hereditary or familial amyloidosis; 5) amyloid associated with endocrine organs; 6) amyloid associated with aging (brain or heart); 7) amyloid associated with chronic hemodialysis; and finally 8) localized amyloid (Table 1). In the past few years,

Table 1 Simplified classification of amyloid

Clinical aspects	Protein or variant or precursor	Amyloid nomenclature
1. Secondary (reactive) Familial Mediterranean fever	apoSAA (precursor)	AA
2. Primary (idiopathic) Multiple myeloma associated	κ or λ chains	AL
3. Familial amyloid polyneuropathy	Transthyretin variant prototype Met 30 (multiple mutations)	ATTR
	Apolipoprotein A variant Arg 26 (multiple mutations)	AApoAI
	Gelsolin Asn 15	AGel
Familial amyloid cardiopathy	Transthyretin Met 111	ATTR
Senile cardiomyopathy	Transthyretin Ile 122	ATTR
4. Alzheimer disease	β protein from amyloid β protein precursor	A β
Down syndrome		
Dutch hereditary cerebral hemorrhage with amyloid		
5. Chronic hemodialysis	β_2 microglobulin	AB ₂ M
6. Adult onset (type II) diabetes mellitus	Islet amyloid polypeptide (IAPP) (amylin)	AIAPP
7. Medullary carcinoma of thyroid	Procalcitonin	ACalc
8. Icelandic hereditary cerebral hemorrhage with amyloid	Cystatin C (trace γ) Gln 68	ACyst
9. Isolated amyloid of the heart (atrium)	Atrial natriuretic factor	AANF
10. Creutzfeldt-Jacob disease	Prion protein (scrapie protein)	AP γ P

it has been demonstrated that while all amyloid has common physical characteristics, biochemically there are multiple proteins, unique for each clinical form of amyloid listed above, and that a variety of proteins with specific point mutations are found in the hereditary dominant forms of the disorder.

Pathogenesis

AA

Secondary amyloid consists of the protein AA (amyloid A) an 8.5 kDa protein that is heterogeneous (at the amino terminal end). It is putatively derived by proteolysis from the normal circulating protein apoSAA (serum amyloid A related protein) which has a molecular weight of 12 kDa. apoSAA is an apolipoprotein associated with high density lipoprotein (HDL) especially HDL₃ and acts as a very sensitive acute phase protein. SAA is polymorphic in mice (four genes and two pseudogenes have been identified) and in man (three genes have been identified). In man SAA₁ isotype appears to be the major contributor to AA while in mice SAA₂ isotype is the sole contributor.

AL

Idiopathic (primary amyloid) and that associated with multiple myeloma consists of whole or partially degraded immunoglobulin light chains (i.e. whole or part of the V_L domain, with a molecular weight of 8–23 kDa). These fragments derived from the amino terminal region are more predominantly λ than κ chains. It has been deduced that some λ structures make the light chain fragments more likely to polymerize as amyloid. Indeed, λ VI was first discovered as an amyloid protein. The identical fragment that constitutes the amyloid deposit may be found in the serum or urine as a monoclonal spike. Cases of heavy chain amyloid have been described.

ATTR

In the prototypic Portuguese (autosomal dominant) familial amyloid polyneuropathy, transthyretin (prealbumin) variants have been found to constitute the amyloid. This molecule circulates as a 55 kDa tetramer composed of 4 identical 127 amino acid monomers. This molecule is a carrier of thyroxine and of retinol binding protein. It also acts as a negative acute phase reactant. It is determined by one gene located on chromosome 18. The most common abnormality is the substitution of methionine for valine at position 30 in families of Portuguese, Swedish,

Japanese, Italian, and Greek origin. Substitutions in the families with other phenotypic expression occur at over 50 other positions. Several different mutations may be present at one position (i.e. 30, 33, 35, 45, 47, 50, 58, 84). Hereditary amyloid composed of variant apolipoprotein A1, of the proteins gelsolin, fibrinogen A α , lysozyme and of β protein have also been described, each in a different clinical syndrome.

AP

Other substances are associated with amyloid. Amyloid P component (AP) has been identified in all forms of amyloid as a molecule independent of the amyloid fibril but nonetheless intimately bound to it. AP is a glycoprotein of molecular weight 22 kDa in its monomeric form. It circulates as SAP (serum amyloid P component), a pentraxin composed of two pentameric units. SAP acts as an acute phase reactant in mice, but is clearly a constitutive protein in humans. Its role in amyloidogenesis is unclear. Do its ligand binding properties make it a focus for fibril deposition or is it an epiphenomenon? Glycosaminoglycans are also intimately associated with amyloid deposits.

AEF

Amyloid enhancing factor (AEF) has been extensively studied in animals and dramatically shortens the induction time for experimental AA deposition in mice. It appears to be a monokine produced by macrophages when stimulated by inflammation. Whether it plays a more pervasive role is yet to be determined.

AB2M

Other forms of amyloid exist. In chronic long-term hemodialysis, patients often develop a carpal tunnel syndrome, arthritis and cystic bone lesions, all due to amyloid. The protein isolated has been β 2 microglobulin, a single chain low molecular weight (11.8 kDa) polypeptide that is continually shed from all membranes. It does not pass through most dialysis membranes and in chronic hemodialysis its concentration may rise 50-fold. The specific local factors influencing its precipitation as amyloid are not yet known.

A β

It has long been known that the senile plaques of Alzheimer disease stain positively for amyloid. The amyloid fibrils of the senile plaque and cerebral amyloid angiopathy from both Alzheimer disease and Down syndrome have been isolated and identified as

β protein (also known as A4 protein), a 4.2 kDa protein (39 amino acid segment isolated from vessels; 43 amino acid segment from plaques). The 28 N-terminal amino acids are almost identical in the senile plaques and vessel. Beta protein is derived from a 695 amino acid glycoprotein of 79 kDa (β amyloid protein precursor A β PP) that crosses and constitutes part of the cell membrane. The precise cause of the cleavage of the A β PP is not known, but aberrant degradation involving serine protease inhibitors such as α 1 antichymotrypsin (ACT) which is regularly found in plaques has been suggested.

ANAPHYLATOXINS

Clemens A Dahinden, Institute of Immunology and Allergology Inselspital, Bern, Switzerland

The term anaphylatoxin stems from the observation, originally made by Friedberger in 1910, that injection of complement-activated serum in small experimental animals, such as guinea pigs, results in an anaphylactoid reaction similar to the symptoms of an acute hypersensitivity shock which occurs after exposure of sensitized animals to the antigen. This acute, potentially lethal, reaction was found to be due to small bioactive fragments, termed anaphylatoxins to describe the functional behavior of these humoral factors. Some of the effects of systemic administration of anaphylatoxins are due to the release of bioactive cell-derived mediators as in hypersensitivity reactions, but the lethal effect is rather related to the potent spasmogenic activity of the anaphylatoxins causing respiratory failure due to acute bronchiolar constriction. It is unlikely that in humans anaphylatoxins have such dramatic effects, although they certainly contribute to the pathogenesis of, for example, septic shock and the acute respiratory distress syndrome (ARDS) in synergy with other proinflammatory factors, such as lipopolysaccharide (LPS) and tumor necrosis factor (TNF). Indeed, high levels of C3a can be detected *in vivo* under these clinical conditions.

Mainly based on their activity on the isolated guinea pig ileum, the anaphylatoxins C3a, C4a and C5a have been isolated from complement-activated serum and their amino acid sequence was determined many years ago. A large number of more recent func-

tional studies, and the characterization of anaphylatoxin receptors, however, clearly established that the anaphylatoxins are typical chemotactic cell agonists. They act in a very similar fashion to other chemotactic agonists, such as the bacterial leader sequence analogue N-formyl-met-leu-phe, the cell-derived lipid mediators leukotriene B₄ and platelet-activating factor, and the very large group of cell-derived chemotactic cytokines, the chemokines. All these agonists act on cells mainly of hematopoietic origin, by interaction with specific, pertussis toxin-sensitive, G_i-coupled seven-transmembrane (serpentine) receptors, and they activate the cells by utilizing very similar signal transduction pathways leading to similar cellular functions. Based on sequence homologies and the similarity in function, the receptors for all chemotactic agonists, including the receptors for anaphylatoxins, constitute a subfamily of the rhodopsin receptor superfamily. It is important to note that, despite this redundancy, the anaphylatoxins are the only well-characterized endogenous humoral inflammatory mediators among this large group of chemotactic leukocyte agonists.

Generation of anaphylatoxins

The anaphylatoxins C3a, C4a and C5a are formed by specific cleavage of a single Arg–X bond in the α chains of C3, C4 and C5, respectively, through the corresponding convertase. The C3, C4 and C5 con-

vertases are formed during complement activation by the classical pathway, the lectin pathway and (C3 and C5 convertases only) the alternative pathway. Thus, by the generation of bioactive activation products, the complement cascade connects recognition systems of the innate and adaptive immune system with effector systems for host defense. A major consequence of the anaphylatoxins generated locally due to tissue injury, infection or immunoglobulin-antigen complexes is to promote an inflammatory reaction. This inflammatory response is primarily due to the capacity of the anaphylatoxins to induce the release of cell-derived vasoactive mediators and to directly attract and activate inflammatory effector cells. C3a and C5a may also be generated without complement activation by certain proteases of the host or from pathogens (e.g. mast cell tryptase and a cysteine proteinase from *Bacteroides gingivalis*, cleaving C3 and C5, respectively).

The C-terminal arginine of the anaphylatoxins is rapidly cleaved by serum carboxypeptidase N, resulting in peptides with negligible (C3a_{desarg}, C4a_{desarg}) or altered (C5a_{desarg}) bioactivity. Thus, the radius and duration of action of C3a is rather short, while the major stable soluble bioactive product of complement activation is C5a_{desarg}. C5a_{desarg} retains sufficient affinity for the C5a receptor to be cleared from the circulation or from inflammatory exudates by receptor-mediated endocytosis. C3a_{desarg} and C4a_{desarg}, however, can be detected in bodily fluids, and assay systems to monitor the levels of these anaphylatoxins have been developed as an efficient and sensitive way to assess complement activation *in vivo*. Because of the central role of C3 in all the complement pathways, C3a is a general parameter of complement activation, while C4a has been regarded as a specific marker for the activation of the classical pathway by immune complexes. The recent discovery of the lectin pathway, which is initiated by recognition of certain carbohydrates on pathogens and which is homologous to the classical pathway, makes this assumption and the clinical utility of C4a measurements less certain. The highest levels of anaphylatoxins are found in acute states such as ARDS, multisystem organ failure and sepsis, where anaphylatoxins may actually contribute to a potentially lethal outcome. However, more subtle changes in anaphylatoxins (C3a or C4a) have been described in a number of clinical patient studies in a variety of (primarily inflammatory) disorders. Complement is also activated by contact of plasma with artificial surfaces *in vivo* and well as *in vitro*. Thus, complement activation *ex vivo* must be carefully monitored when collecting blood samples. Furthermore, significant complement activation occurs during

extracorporeal blood treatment by cardiopulmonary bypass surgery and dialysis, probably contributing to side-effects and complications of these procedures. Progress in decreasing complement activation by artificial surfaces has allowed an increase in the biocompatibility of such membranes.

Structure of anaphylatoxins

The complement fragments C3a, C4a and C5a released during complement activation are, in humans, 77–74 amino acid residues in length, and share, as their parent proteins C3, C4 and C5, significant homology in their primary sequence. They all have a core with three disulfide bridges. More importantly, crystallographic data of C3a and nuclear magnetic resonance (NMR) studies of C3a and C5a in solution showed that C3a and C5a have very similar secondary and tertiary structures. The first 63 residues of C5a in solution form an antiparallel bundle of four helices similar to the coiled-coil arrangement of helices in many other four-helix proteins, while the C-terminus is disordered. The helices I, II, and IV are quite regular and are compatible with an α -helical pitch. The N-terminal helix is amphiphilic and its hydrophobic residues are interdigitated with hydrophobic residues on helices II and IV. The structure of C5a seems to differ somewhat from the crystal structure of C3a, which shows a disordered N-terminus and a helical C-terminus, but NMR investigations of C3a in solution indicate that the terminal regions of both anaphylatoxins are similar.

Thus, based on similarities of bioactivity, of their receptors as well as of their structure, the anaphylatoxins must be regarded as a family of closely related molecules. Anaphylatoxins of other species are most likely very similar in structure as well. Furthermore, the bioactivity of C3a and C5a is not species restricted, as is the case for many cytokines. Human C5a has, however, some notable peculiarities. First, there is a N-terminal odd cysteine at position 27 in the loop connecting helix II with helix III, facing towards the solvent. It can be attached to molecules such as glutathione without effect on bioactivity, and it may covalently link to other proteins with a free accessible -SH group under an oxidative environment. Indeed, yet poorly defined high molecular weight chemotactic factors have been described in serum. Second, a bulky sugar moiety is attached in human C5a near the C-terminus which is of major importance in receptor activation. This glycosylation may be responsible in part for the fact that natural human C5a_{desarg} is a potent chemoattractant but a very ineffective cell activator and spasmogen.

C3a and C4a receptors

It is still unclear whether C3a and C4a mediate their effects by common or separate receptors. Based on their activity and cross-desensitization on the guinea pig ileum contraction assay, C4a has been regarded as a weak C3a receptor agonist. This assumption requires confirmation on cells transfected with the C3a receptor. Other less conclusive data on guinea pig macrophages indicate that there may be separate receptors.

The C3a receptor could not be identified until recently, although C3a was isolated decades ago. Despite this lack of a defined cellular model, extensive investigations, mainly by T Hugli and coworkers in the heterologous guinea pig system, established the structure-function relationships of C3a analog peptides and identified the C-terminal pentapeptide as a full C3a receptor agonist. Further studies revealed that the C-terminal 21-residue fragment is nearly as potent as the complete anaphylatoxin, and, by attaching several hydrophobic residues to the N-terminus of a synthetic peptide based on the 12–13 residue C-terminal fragment of C3a, superagonists of even greater potency than the natural factor were obtained (Figure 1). Thus, the interaction of C3a with its receptor is clearly less complex than that of C5a and probably most other protein ligands of seven-transmembrane receptors.

The human C3a receptor has recently been cloned by two independent groups. It is a typical seven-transmembrane receptor of the chemotactic factor subfamily. As for other chemotaxin receptors, activation of the C3a receptor in transfected cells promotes a transient elevation of cytosolic calcium concentration by a pertussis sensitive G_i -coupled activation of phospholipase C. In contrast to other G protein-coupled receptors, the C3a receptor carries an unusually large second extracellular loop of over 160 amino acids of unknown function. Neglecting this loop, the C3a receptor is most closely related to the C5a and fMLP receptor, with 37% and 34% homology, respectively. The C3a receptor mRNA is widely expressed in peripheral blood lymphocytes, different lymphoid tissues as well as in different solid organs. The identification of the receptor for C3a will now permit better characterization of the role of this anaphylatoxin in homeostasis and host defense, and will aid in the development of specific antagonists.

C5a receptors

The C5a receptor was cloned independently by two groups several years ago, and was shown to be a G

Figure 1 (Upper) The helical region of the C-terminal end of C3a is shown with the hydrophobic patch outlined (dashed line) including residues Tyr59, Ile60 and Leu63. This patch is believed to interact with a hydrophobic sub-binding site of the C3a receptor. The superpotent synthetic analog of C3a has two tryptophan residues substituted for the hydrophobic patch on the natural factor. The residues that are underlined are nonessential replacements that improve solubility of the analog. (Lower) The schematic model illustrates how the natural factor C3a and the synthetic analog C3a 57–77 interacts with the receptor. The hypothesis is that the model Trp-containing superpotent peptide mimics C3a by interacting with the receptor in a similar manner. Interaction at the hydrophobic sub-binding site cooperatively enhances binding of the essential Leu-Gly-Leu-Ala-Arg effector site. If binding of Trp-Trp at the hydrophobic site is greater than the Tyr-Ile-Leu patch, it could explain the superpotency of the analog peptide.

protein coupled seven-transmembrane receptor of 350 residues in length with high (34%) homology to the fMLP receptor. This has allowed a detailed molecular characterization of ligand–receptor interaction using monoclonal antibodies and mutants of both C5a and its receptor. Furthermore, based on weak binding of the C-terminal octapeptide of C5a to the C5a receptor, several peptide analogs with reasonable affinity and agonistic, partial agonistic or antagonistic properties were developed. These studies led to a two-binding model of ligand–receptor interaction, as first proposed by MS Springer (Figure 2). One involves the core of C5a (with participation of Lys19 and Lys20) interacting with the extracellular N-terminus (in particular with several aspartic acid residues in this region), presumably resulting in a conformational change of C5a, which allows its C-

terminus to interact with a second, ill-defined, binding site in a transmembrane segment. Using synthetic C5a hexapeptide analogs and mutant receptors, an interaction of the peptide C-terminal arginine with Arg206 in the fifth transmembrane helix of the receptor has been proposed as a mechanism to activate this second binding site. It should be noted, however, that C5a_{desarg}, which has no C-terminal arginine, is a potent chemoattractant, but is rather ineffective in activating many other cell functions, indicating that different types of ligand–receptor interactions exist which lead to distinct signaling events.

Bioactivity of anaphylatoxins

C3a

While most of the earlier investigations on C3a bioactivity dealt with its spasmogenic and vasoactive properties *in vivo* and in tissues of experimental animals, more recent studies revealed that the effect of C3a is not so much different from that of other chemotactic agonists. However, the target cell profile of C3a is more restricted than that of C5a. C3a induces calcium transients in all myeloid cells indicating wide expression of C3a receptors on leukocytes, although C3a has negligible effects on the function of monocytes and neutrophils. C3a is a chemoattractant and potent inducer of exocytosis for eosinophils. The efficacy of C3a in inducing the release of cytotoxic products is similar to that of C5a and clearly higher than that of chemokines, such as eotaxin. C3a also induces mediator release in cytokine-primed basophils and in mast cells from the skin but not from the lung, while the effects on mast cells from other sites (e.g. intestine, heart, uterus) are largely unknown. These data indicate that C3a may be important in allergic inflammation and other conditions involving mast cells, eosinophils and basophils. C3a_{desarg} cannot activate the C3a receptor. High levels (around 10 μM) of C3a_{desarg} seem to directly activate G proteins similar to other cationic peptides, such as mastoparan. The biological meaning of this effect is uncertain, although such high levels can theoretically be achieved *in vivo*.

C5a

C5a is a classical and most potent and effective chemoattractant and activator of effector functions of different leukocyte types, and, among the different chemotaxins, the effects are most similar to that of fMLP. Unlike chemokines, which have a more restricted target cell profile, C5a is rather pleiotropic and acts efficiently on neutrophils, monocytes, macrophages, eosinophils, basophils, dendritic cells

Figure 2 Model for the binding of C5a to its receptor. As shown in (B), the interaction takes place at distinct sites. The first, designated site 1, is between the N-terminus, and possibly the second extracellular loop of the receptor, and the core of C5a. Specifically, primary interaction is thought to be between several of the aspartic acid residues in the N-terminus and Arg40 and possibly Arg37 and His15 of C5a. The second interaction site, designated site 2, is between the C-terminus of C5a and the interhelical region of the receptor. The primary interaction involves Arg74 and Lys68 of C5a. The initial site of productive contact is believed to take place at site 1, as depicted in (A). The contact at site 1 effectively raises the local concentration of C5a and thereby promotes the more difficult interaction at site 2. (Reproduced from Siciliano *et al* (1994).)

and possibly some lymphocyte subpopulations. Neutrophil responses to C5a have been most extensively studied and shown to include the induction of calcium transients, shape change, cell polarization and chemotaxis, upregulation of receptors, integrin activation and, at higher concentrations, exocytosis, oxygen radical production, induction of a hyperadhesive state and enhancement of phagocytic and cytotoxic functions. Furthermore, after priming with the appropriate cytokine – granulocyte-macrophage colony-stimulating factor (GM-CSF) for neutrophils and monocytes, interleukin 3 (IL-3), IL-5 and GM-CSF for basophils and eosinophils – C5a promotes the synthesis of large amounts of the lipid mediators leukotriene B₄ (LTB₄), platelet-activating factor (PAF), and LTC₄. Together with fMLP, C5a induces the broadest range of biological responses in effector cells, in contrast to most other chemotactic agonists which more preferentially activate either chemotaxis or cell activation, indicating important, yet ill-defined, differences in receptor signaling. Interestingly, C5a_{desarg} is a poor activator of most leukocytes, but retains potent chemotactic activity, thus becoming more similar to other chemotaxins such as IL-8 and LTB₄. The bioactivity of C5a_{desarg} also depends on the cell type: it is still chemotactic for a broad range of leukocytes, yet stimulates efficient exocytosis only in basophils, but not in mast cells or mast cell lines. The reason for this complexity is unknown.

Cytokine expression and immunoregulation

More recent studies have shown that C5a in synergy with LPS promotes expression of IL-1 and IL-6 in monocytes. Combined stimulation of basophils with IL-3 and C5a induces the selective expression of IL-4 and IL-13, which are key immunoregulatory cytokines for the induction of a T_H2-type immune response and for the synthesis of immunoglobulin E (IgE). C5a is unique in this respect, as other chemotactic agonists, such as chemokines which are also effective triggers of chemotaxis and/or exocytosis, are unable to induce cytokine expression. Thus, C5a is not just an inflammatory mediator but may also have indirect immunoregulatory properties, and promote humoral and T_H2 type immune responses. These observations also emphasize the importance of studying the effects of anaphylatoxins within the network of other factors.

Activities outside the immune system

C5a also acts on liver cells and induces the expression of acute phase proteins. Furthermore, the mRNA for the receptors for C5a and C3a are widely expressed in a large number of tissues and organs, indicating that anaphylatoxins may have other, largely unexplored, functions outside the immune system. Particularly abundant transcripts for the C5a receptor are found in lung, spleen, heart, placenta, spinal cord and throughout the brain, and for the C3a receptor in lung, spleen, ovary, placenta, small intestine and less ubiquitously in the brain.

ANEMIA, AUTOIMMUNE HEMOLYTIC IN ANIMAL MODELS

C J Elson and **C-R Shen**, Department of Pathology and Microbiology, University of Bristol, Bristol, UK

Autoimmune hemolytic anemia (AIHA) is a classic example of an antibody-mediated autoimmune disease. It is well documented how autoantibody-coated red blood cells (RBCs) can be destroyed by splenic macrophages, but by contrast, the mechanisms that initiate the production of RBC autoantibodies remain unclear. The New Zealand Black (NZB) strain of mice spontaneously develops AIHA. RBC-bound immunoglobulin G (IgG) autoantibodies can be detected by Coombs' test from 3 months of age and the mice develop signs of anemia 2–3 months later. For two decades after these mice were first bred in 1959, a flood of papers appeared documenting the specificity of the autoantibodies and attempting to pinpoint lesions in particular cells which could result in the generation of RBC autoantibodies. Many of these results are now open to re-evaluation in the light of recent studies.

Antigen specificity of RBC autoantibodies from NZB mice

Historically, four distinct RBC autoantigens were described in NZB mice, namely X, HB, I and HOL. The IgG response to the antigen designated X appears to be of primary pathogenic importance, since only antibodies of this specificity are exclusive to the NZB mouse and are capable of binding untreated murine RBCs, i.e. to determinants normally exposed on the RBC surface. By contrast, IgM autoantibodies reactive with the antigens HB and I, and IgG antibodies specific for HOL are also found in strains of healthy mice, and recognize cryptic epitopes on the RBC membrane. Recent work has confirmed that antibodies eluted from the RBCs of old, anemic NZB mice are pathogenic when injected into younger animals with prepatent disease. Moreover,

as judged by immunoprecipitation, the target of these antibodies is band 3, the RBC anion channel protein. These results would suggest therefore that X is band 3.

One approach to understanding the pathogenesis of AIHA in NZB mice is to prepare and characterize hybridoma antibodies derived from spleen cells of anemic animals. A number of such monoclonal antibodies that react with intact murine RBCs have been generated and their properties examined in detail. For example, analysis of the variable region gene usage of NZB-derived RBC-specific monoclonal antibodies reveals evidence of somatic mutation, consistent with an antigen-driven response. Some of the monoclonal antibodies are pathogenic *in vivo*. Injection of pathogenic IgG monoclonal antibodies into mice induces hemolysis by Fc-dependent erythrophagocytosis, whereas massive accumulations of hemagglutinated RBCs are found in the recipients of pathogenic IgM monoclonals. It should be noted that hemagglutinated RBCs are not prominent on histological examination of spleens from anemic NZB mice.

The erythrocyte autoantigens recognized by a panel of eight hybridoma RBC autoantibodies were recently characterized. Two of the three pathogenic IgG monoclonal antibodies immunoprecipitated band 3. A third nonpathogenic IgG monoclonal also precipitated band 3 but only at high concentrations. This monoclonal was the only one to react with band 3 by immunoblotting and it alone of the IgG monoclonals reacts with RBCs from other species. None of the four IgM monoclonal antibodies precipitated any labeled RBC components. However, by immunoblotting, the two pathogenic IgM monoclonals bound to a doublet which corresponds in electrophoretic mobility with band 4.1 from the

internal RBC membrane skeleton. An explanation of how these antibodies bound intact RBCs may come from the finding that they also bound to histones, suggesting that they are polyreactive and recognize surface autoantigens such as phospholipids. Thus, the demonstration that two pathogenic monoclonal autoantibodies recognize band 3 confirms that this protein bears important autoantigenic epitopes but also reveals that some pathogenic monoclonal antibodies do not share this characteristic. It could be argued that the latter monoclonal antibodies represent minor components of the total RBC autoantibody population or that antibodies to multiple RBC antigens, in addition to Band 3, contribute to hemolysis in NZB mice.

Transgenic mice

Honjo and his colleagues generated transgenic mice expressing one of the pathogenic IgM monoclonal antibodies derived from NZB mice. In these mice conventional (B-2) B cells were deleted, presumably after contact with RBCs, but normal numbers of CD5 B-1 cells were present in the peritoneal cavity and lamina propria. About 50% of these mice developed AIHA in a conventional environment but not if maintained in isolators. Oral administration of LPS induced AIHA in asymptomatic anti-RBC transgenic mice but not in transgenic mice bearing the *xid* (B-1 cell deficient) mutation. Since intraperitoneal injection of RBC into the transgenic mice induced apoptotic death of peritoneal B-1 cells and prevented AIHA developing, it appears that RBC-reactive B-1 cells survive in the RBC-free regions of the peritoneal cavity and gut and are stimulated by microorganisms to produce RBC autoantibodies. Are these findings relevant to NZB disease? It has been known for some years that the introduction of the *xid* mutation into NZB mice reduces the production of RBC autoantibodies and the development of anemia. The therapeutic effect of the *xid* gene could result not only from the lack of B-1 cells but also from defects introduced into conventional B cells. However, NZB mice injected intraperitoneally with distilled water weekly from birth to 12 months of age have markedly reduced splenic B-1 cells, increased hematocrit values and reduced levels of RBC-bound IgG and IgM. These results suggest that B-1 cells contribute directly to the development of NZB disease by secreting IgM RBC autoantibodies and that some IgG RBC autoantibody-secreting cells are derived, directly or indirectly, from B-1 cells.

Ontogenesis of RBC autoantibody response

Early work showed that neonatal thymectomy of NZB mice failed to prevent the generation of RBC autoantibody, although thymectomy immediately after birth appeared to delay the onset of autoantibody production. It was also established that RBC autoantibody production can be transferred to irradiated non-NZB H-2^d recipients with bone marrow cells. Since the anti-RBC plaque-forming response still occurred in chronically T-depleted recipients, it was argued that an intrinsic defect was present in NZB B cells and implied that the RBC autoantibody response was T-independent. Recent work calls these interpretations into question. First, SCID mice repopulated with NZB pre-B cells fail to develop RBC autoantibodies despite that fact that high levels of IgM anti-DNA and low levels of IgG anti-DNA are generated. Secondly, chronic treatment of NZB mice with monoclonal anti-CD4 prevents or considerably delays the generation of RBC autoantibodies. Interestingly, anemia still occurs in anti-CD4-treated NZB mice, possibly because they developed an ulcerative colitis. Finally, Gershwin and his colleagues have generated CD4 and CD8 gene-deleted NZB mice. Again the incidence and titers of RBC autoantibodies (particularly of the IgM isotype) were significantly reduced in NZB.CD4^{-/-} mice as compared with wild-type NZBs. By contrast, no significant change in RBC autoantibody responses was observed in NZB.CD8^{-/-} mice. Thus CD4⁺ T cells clearly contribute to the development of NZB AIHA.

Specificity and characterization of T cells

Since the generation of pathogenic anti-RBC autoantibodies is CD4 T lymphocyte dependent, it would be predicted that NZB mice harbor helper T cells responsive to RBC autoantigens. Splenic T cells from NZB mice, but not other H-2^d strains such as BALB/c or DBA2 mice, do indeed proliferate *in vitro* in response to band 3. The majority of the responding cells express CD4 and the response is major histocompatibility complex class II restricted. Thus the T cells which help the production of the band 3 reactive autoantibodies may also be band 3 specific. The epitopes which stimulate band 3-reactive T cells have been mapped. Splenic T cells from old NZB mice respond to some 20 15mer peptides corresponding to the sequence of band 3. However, the response to one peptide is dominant in terms of magnitude and the appearance of the response with age. Splenic T cells from NZB mice as

young as 3 weeks old respond to this peptide but generally not to others, suggesting that the response is initially focused on the dominant peptide and later spreads to other band 3 epitopes. So far attempts to demonstrate that band 3-reactive T cells are present and primed in the thymus have failed. Thus band 3-reactive T cells may be primed in the periphery. Nevertheless, the observation of abnormalities in the structure of the NZB thymus suggests that events in the thymus should not be neglected.

CD4⁺ T cells can be classified into two types, T_H1 and T_H2, depending on the cytokines they produce. For example, T_H1 cells typically secrete interferon γ (IFN γ) and T_H2 cells interleukin 4 (IL-4). The type of cytokine secreted by helper T cells affects the isotype of antibody produced, and in mice T_H1-dominated responses are associated with IgG2a antibodies and T_H2 with IgG1. Whilst there is now a consensus that pathology of cell-mediated autoimmune diseases is linked to the stimulation of T_H1 autoreactive cells, it might be expected and indeed it has been suggested that T_H2 responses may be important in initiating and driving antibody-mediated autoimmune disorders such as AIHA. However, NZB T cells stimulated with band 3 produced high levels of IFN γ , but little or no IL-4, IL-5 or IL-10. Similar patterns were produced by NZB T cells responding to a spectrin preparation from the RBC membrane skeleton, or to mycobacterial heat shock protein (hsp) 65 following immunization of mice with hsp65 in incomplete adjuvant. By contrast, T cells from CBA mice similarly immunized with hsp65 produced high levels of IL-4 and IL-5 in response to hsp65.

Examination of the isotype of the RBC-bound immunoglobulins in NZB mice revealed that IgG2a autoantibodies were the first to be detected in most mice and that later in the disease, IgG3 autoantibodies were often prominent. Consequently, contrary to expectation, the development of RBC autoantibodies in NZB mice is associated with T_H1 cytokine-dominated responses. How T_H1 cytokines effect NZB disease remains to be determined, although it has been suggested that T_H1 cytokines can alter antigen processing so that previously cryptic epitopes become presented and are thus responsible for epitope spreading.

ANEMIA, AUTOIMMUNE HEMOLYTIC IN HUMAN

Alan D Schreiber, Department of Medicine, Hospital of the University of Pennsylvania, Philadelphia, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The autoimmune hemolytic anemias represent a group of disorders in which individuals produce antibodies directed toward one or more of their own erythrocyte membrane antigens. This in turn leads to destruction of the erythrocytes. An effective manner in which to approach autoimmune hemolytic anemia is to analyze which class of antibody is responsible for the hemolysis. In general, there are two major classes of antierythrocyte antibodies which produce hemolysis in humans: immunoglobulin G (IgG) and IgM. The pattern of red blood cell clearance, the site of organ sequestration, the response to therapy, and the prognosis all relate to the class of antierythrocyte antibody involved.

IgM-induced immune hemolytic anemia

Autoimmune hemolytic anemia caused by IgM antibody in humans is generally restricted to the clinical entity of cold hemagglutinin disease, in which the antibodies only bind significantly to the erythrocytes at temperatures below 37°C. The most common form of chronic cold hemagglutinin disease is the primary or idiopathic form caused by an IgM antibody. This is a clonal disorder and is associated with the presence of a monoclonal IgM antibody which usually has a high cold agglutinin titer. The IgM antibody is usually directed against the I antigen or related antigens on the human erythrocyte membrane. As with all IgM antibodies agglutinating activity is particularly efficient because of the multiple antigen combining sites on the IgM molecule. The cold agglutinin titer represents the least dilution of patient plasma or serum capable of agglutinating human red blood cells in the cold. In most patients with hemolysis the cold agglutinin titer is greater than 1:1000.

Secondary cold hemagglutinin disease is most commonly associated with an underlying mycoplasma infection, particularly *Mycoplasma pneumoniae*. It may also occur with other infections, such as infectious mononucleosis or cytomegalovirus. Cold hemagglutinin disease (IgM-induced immune hemolytic anemia) can also be seen with an underlying immunoproliferative disorder, such as chronic lymphocytic leukemia, non-Hodgkin's lymphoma, or systemic lupus erythematosus. The disease may be chronic and the IgM protein may be of restricted het-

erogeneity (oligoclonal) or even be monoclonal. When this is the case, one should suspect an underlying malignant immunoproliferative disorder and the prognosis is adversely affected.

As in all patients with autoimmune hemolytic anemia, erythrocyte survival is generally proportional to the amount of antibody on the erythrocyte surface. In cold hemagglutinin disease the extent of hemolysis is a function of the titer of the antibody (cold agglutinin titer), the thermal amplitude of the IgM antibody (the highest temperature at which the antibody is active), and the level of the circulating control proteins of the C3b inactivator system. Hemolysis is complement-dependent and the IgM-coated erythrocytes become coated with C3b by classical complement pathway activation. These C3b-coated erythrocytes are cleared primarily by the macrophage C3b receptors in the liver. Two uncommon variants of cold hemagglutinin disease, low IgM titer cold hemagglutinin disease and cold hemagglutinin disease mediated by IgG antibody are more responsive to therapy.

IgG-induced immune hemolytic anemia

In IgG-induced immune hemolytic anemia, the antibodies are of the IgG class and the antigen to which the antibody is directed is usually an Rh erythrocyte antigen. The antibody has its maximal activity at 37°C, and, thus, this entity has been termed warm antibody-induced hemolytic anemia. IgG-induced immune hemolytic anemia may occur without an apparent underlying disease (idiopathic type); however, it may also occur with an underlying immunoproliferative disorder, such as chronic lymphocytic leukemia, non-Hodgkins lymphoma or systemic lupus erythematosus. The signs and symptoms are those of anemia in general. The diagnosis is established by directly examining the erythrocyte surface for the presence of IgG and C3b.

In addition to C3b receptors, macrophages within the reticuloendothelial system have receptors for the Fc fragment of IgG, called Fcγ receptors. The macrophage Fcγ receptors can detect IgG-coated erythrocytes, bind them, make them spherical, or phagocytose them in the absence of C3b. However, once C3b is placed on the erythrocyte surface, through com-

plement activation, erythrocyte clearance is further accelerated. Thus, IgG-coated erythrocytes are progressively cleared from the circulation by macrophages possessing Fc γ receptors. Hemolysis is almost always extravascular and these IgG-coated cells are cleared predominantly in the spleen. Complement activation accelerates the clearance of IgG-coated cells.

Drug-induced immune hemolytic anemia

Drug-induced immune hemolytic anemia can be divided into four major pathophysiologic groups. Clinical signs and symptoms are identical to those of the other autoimmune hemolytic anemias. The diagnosis is established primarily by history.

Hapten type

This type of drug-induced immune hemolysis classically develops in patients exposed to high doses of penicillin. A portion of the penicillin molecule or its active metabolites combines with the erythrocyte surface, acting as a hapten. This induces an antibody response directed against the penicillin-coated erythrocyte membrane. This is usually an IgG response, and complement activation is common. The patient's erythrocytes become coated with IgG and often with C3. Patients rarely develop this syndrome unless they have received 10–20 million units of penicillin a day. Diagnosis can be established by incubating the patient's serum with donor erythrocytes preincubated with penicillin. The deposition of IgG antibody will occur only in the presence of penicillin and can be detected with the Coombs test.

Quinidine type

This type of autoimmune hemolytic anemia most commonly occurs with the use of quinidine or its derivatives. Commonly called an innocent bystander reaction, it is believed to be due to an antibody directed against quinidine bound to a plasma protein or the red blood cell membrane acting as a hapten. This interaction results in activation of the classic complement pathway and deposition of C3 on the erythrocyte surface. With quinidine it is commonly caused by IgM antiquinidine antibody. The diagnosis can be established *in vitro* by examining for complement deposition on donor erythrocytes by patient serum which occurs only in the presence of the drug, e.g. quinidine.

α -Methyldopa type

α -Methyldopa and its derivatives produce a clinical syndrome virtually identical to IgG-induced immune

hemolytic anemia. The mechanism of the IgG antibody formation is poorly understood. Many patients, up to 25%, exposed to α -methyldopa, develop a positive Coombs' test for IgG. These IgG antibodies have specificity for Rh antigens. Most patients do not develop sufficient IgG coating for hemolysis; however, hemolysis is observed in approximately 0.8% of patients exposed to α -methyldopa. Diagnosis can be made by examining the patient's red blood cells and plasma. *In vitro* it is not necessary to have the drug present for the patient's plasma to deposit IgG antibody on donor erythrocytes. A similar syndrome has been reported with mefenamic acid.

Nonspecific coating

Nonspecific coating of the erythrocyte surface has been observed with the antibiotic cephalothin, in which cephalothin becomes bound to the erythrocyte membrane and causes the red blood cells to be coated by many plasma proteins. The Coombs test is positive, but hemolytic anemia is rare. Cephalosporins, however, can cause hemolytic anemia by acting as a hapten by a mechanism similar to that of penicillin.

In all these situations, the patients respond to withdrawal of the offending drug. If necessary, a brief course of glucocorticoid therapy can be effectively administered.

Therapeutic measures

In many patients with IgG- or IgM-induced immune hemolytic anemia, no therapeutic intervention is necessary, since the hemolysis may be mild. If an underlying disease is present, control of this disease often brings the hemolytic anemia also under control. However, if the patient is having significant anemia secondary to hemolysis, therapeutic intervention is in order.

Glucocorticoids

Patients with IgG-induced immune hemolytic anemia usually respond to glucocorticoid therapy in dosages equivalent to 40–120 mg of prednisone a day. Glucocorticoids work in IgG-induced hemolytic anemia by three primary mechanisms. First, they decrease the production of the abnormal IgG antibody. This is the most common effect and produces a gradual increase in hemoglobin within 2–6 weeks. Second, glucocorticoids have in several cases been demonstrated to cause the elution of IgG antibody from the erythrocyte surface, improving the red blood cell survival. This is probably an uncommon effect of therapy.

Third, glucocorticoids have been shown *in vitro* and *in vivo* to interfere with the macrophage Fc γ and to a lesser extent C3b receptors responsible for the erythrocyte destruction in this disease. This effect may be rapid and is probably responsible for the rise in hemoglobin which occurs in some patients within 1–4 days of therapy. This action of glucocorticoids causes an improvement in erythrocyte survival despite the continued presence of IgG and C3b on the erythrocyte surface.

Once a therapeutic response is achieved, tapering of glucocorticoids should be initiated. This may take several months. Alternate-day glucocorticoid therapy may be utilized during this time, or until the patient's hematologic picture stabilizes.

Since glucocorticoids may improve erythrocyte survival by interfering with macrophage detection of IgG-coated erythrocytes, the patient's Coombs test may remain positive in the face of an improved erythrocyte survival. Thus, some patients may continue to improve hematologically despite a persistently positive Coombs' test.

Approximately 80% of patients have an initial response to high-dose glucocorticoids. Nevertheless, only 20–30% have a sustained response following discontinuation of therapy. Several patients maintain control of their hemolytic process on low- or medium-dose glucocorticoid therapy. For the patients who are steroid dependent, the initial and long-term side-effects of steroids must be considered. These include gastritis, peptic ulcer disease, emotional lability, exacerbation of diabetes and hypertension, electrolyte imbalance, increased appetite and weight gain, moon-like faces, osteoporosis, myopathy and increased susceptibility to infection. The severity of these side-effects relates to both dosage and duration of therapy. Splenectomy is usually recommended for patients who are unresponsive to steroids or who require more than 10–20 mg per day or 20–25 mg every other day for maintenance. Each patient requires individual evaluation of underlying disease, surgical risk, extent of anemia and steroid intolerance. In some patients the presence of a mild hemolytic anemia may be preferable to splenectomy or other treatment options. The initial goal of therapy is to return the patient to normal hematologic values with nontoxic levels of glucocorticoid therapy. However, in some patients, a secondary goal of achieving improvement in hemolysis to a clinically asymptomatic state with minimum glucocorticoid side-effects is more realistic. Alternate-day glucocorticoids are worthy of consideration in many patients. Their efficacy is not generally appreciated.

Glucocorticoids are not usually effective in cold hemagglutinin disease. This is probably due to the

fact that these patients generally have large amounts of IgM antierythrocyte antibody and large amounts of C3b on the erythrocyte surface. In addition, some of the hemolysis may be intravascular. A few patients with a low titer cold hemagglutinin disease syndrome, in which the IgM antierythrocyte antibody is active at temperatures approaching 37°C, and patients with cold hemagglutinin disease mediated by IgG antibodies, do respond to glucocorticoid therapy. Patients with cold hemagglutinin disease respond best to the avoidance of cold and control of their underlying disease. Fortunately, in many patients hemolytic anemia is mild.

Splenectomy

The reticuloendothelial system of the spleen with its resident macrophages is the major site for sequestration of IgG-coated blood cells. This appears to be due to the unique circulatory pathways in the spleen whereby hemoconcentration occurs in the splenic cords. This results in intimate contact between macrophages (with their membrane Fc γ receptors) and IgG-coated blood cells in the presence of a minimal amount of plasma IgG; plasma IgG competitively inhibits the macrophage Fc γ receptor binding of IgG-coated cells. Thus, the spleen is usually the major site of red cell sequestration in autoimmune hemolytic anemia, with the liver accounting for a variable degree of sequestration.

Removal of the major site of red cell destruction is an effective therapeutic strategy in IgG-induced immune hemolytic anemia. The response rate to splenectomy is approximately 50–70%; however, the vast majority of the responses are partial remissions. The partial remissions are often quite helpful in that they result in a lessening of the hemolytic rate, with a rise in the hemoglobin value, and/or allow for a reduction in the amount of glucocorticoid needed to control the hemolytic anemia. Patients who are unresponsive to glucocorticoids, require moderate to high maintenance doses of glucocorticoids, or have developed glucocorticoid intolerance are generally candidates for splenectomy. ⁵¹Cr-labeled red cell kinetic studies are probably not beneficial, since the procedure is time consuming, expensive and not a reliable indicator of response to splenectomy.

Splenectomy is effective in IgG-induced hemolytic anemia because the cells are cleared primarily in the spleen. In addition, it has been shown that splenectomy can decrease the production of the IgG-antierythrocyte antibody, as the spleen contains a large B cell pool. Those patients in whom splenectomy fails are probably those with very high concentrations of IgG on the erythrocyte surface; in such

patients the liver plays a more prominent role in clearance.

Splenectomy is not effective in patients with traditional cold hemagglutinin disease because IgM-coated erythrocytes are cleared predominantly in the liver, not in the spleen. An occasional case in which a patient with an apparent IgM-induced hemolytic anemia responded to splenectomy has been reported. This may be due to decreased production of IgM antibody by the spleen in these patients. Patients with the uncommon IgG-induced cold hemagglutinin disease syndrome do, however, respond to splenectomy.

The side-effects of splenectomy vary greatly from institution to institution. We have generally attempted to identify one or two surgical colleagues who carry out most of the splenectomies on our patient population. This experience enhances both the surgical procedures (speed and safety) and the postoperative follow-up. Postoperative thromboses and infection both above and below the diaphragm can occur. The risk of morbidity and mortality is greater in older patients, in those with unrelated underlying disease (benign or malignant immunoproliferative disorder), in those with unrelated medical problems, and, to some extent, is influenced by the degree of glucocorticoid side-effects. Thus, a thoughtful analysis of the benefit-versus-risk factors needs to be undertaken for each patient. A final consideration is that adults who undergo splenectomy may, in rare instances, have a propensity to life-threatening infection, particularly with *Pneumococcus*. For this reason it is generally recommended to immunize patients with Pneumovax some weeks prior to elective splenectomy in an effort to reduce this long-term complication.

Immunosuppressive agents

Several chemotherapeutic agents with known immunosuppressive effects have been used to treat immune hemolytic anemia. The drugs most commonly used include the thiopurines (6-mercaptopurine, azathioprine and thioguanine) and alkylating agents (cyclophosphamide and chlorambucil). Immunosuppressive therapy may be effective for treating patients with IgG-induced immune hemolytic anemia when patients are refractory to steroids or splenectomy. Immunosuppressive agents work by decreasing the production of antibody, and therefore it generally takes at least 2 weeks before any therapeutic result is observed.

Patients are selected for immunosuppressive therapy because they have a clinically unacceptable degree of hemolytic anemia resistant to glucocort-

icoid and splenectomy treatment. Alternatively, they may be intolerant of, or resistant to, glucocorticoids and poor surgical risks for splenectomy. Clinical benefit has been noted in about 50% of patients. A reasonable trial of this type of agent is about 3–4 months, and if no beneficial effect is noted, therapy is discontinued. If clinical benefit occurs, one can maintain the dosage level for a total of 6 months and then taper over several months. During therapy, patients are instructed to maintain a high fluid intake to reduce the incidence of chemical cystitis seen with cyclophosphamide and the need to have weekly blood counts to monitor bone marrow suppression, which can be seen with any of these immunosuppressive drugs. Dosage should be adjusted to maintain the leukocyte count >2000 , granulocyte count >1000 and platelet count $>50\,000$ – $100\,000\text{ mm}^{-3}$.

Cyclophosphamide in this dosage range is usually well tolerated but a variety of side-effects may occur, including bone marrow suppression (primarily leukopenia), hemorrhagic cystitis, nausea, partial alopecia, amenorrhea and impaired spermatogenesis. The use of alkylating agents may also have long-term potential for increasing the incidence of malignancy, particularly acute leukemia. These side-effects require that the clinical indications for immunosuppressive therapy be strong and that patient exposure to the drug be limited.

Aside from supportive measures, immunosuppressive therapy has been the major therapy in traditional high titer IgM induced cold hemagglutinin disease. Alkylating agents (cyclophosphamide or chlorambucil) have been the primary drugs used and appear to have a beneficial effect in up to 50–60% of cases. Unresponsiveness is probably due to the fact that very little antibody is required for significant hemolysis to occur.

Miscellaneous therapy

Plasmapheresis has been used in patients with severe IgG-induced immune hemolytic anemia but has met with limited success, possibly because more than half of the IgG is extravascular and the plasma contains only small amounts of the specific antibody (most of the antibody being on the red blood cell surface). However, plasmapheresis has been effective in IgM-induced hemolytic anemia. This is only of short-term benefit, but has reduced the level of cold agglutinins by virtue of the fact that IgM is a high molecular weight molecule that remains predominantly within the intravascular space.

Other measures that have been used effectively are vincristine and vinblastine infusions, gamma globulin infusion and hormonal therapy. Gamma globulin

infusion is effective in IgG-induced immune hemolytic anemia, probably by primarily inhibiting the clearance of the IgG-coated cells. In hormonal therapy the synthetic androgen danazol has been effective in several patients. Because of the limited side-effects (limited masculinizing effects, mild weight gain), danazol or a similar agent may become an attractive alternative to glucocorticoid therapy in some patients with IgG-induced immune hemolytic anemia. However, danazol does not appear effective in IgM-induced hemolytic anemia. The data suggest that one mechanism of danazol's effect is through modulation (inhibition) of macrophage Fc γ receptor expression. Hormonal influence of macrophage Fc γ receptor expression probably explains, at least in part, the increased clinical activity of IgG-induced immune hemolytic anemia during pregnancy. During pregnancy, blood estrogen levels increase to an extent where they enhance splenic macrophage Fc γ receptor expression and thereby accelerate the clearance of IgG-coated cells.

Supportive transfusion therapy

The majority of patients with autoimmune hemolytic anemia do not require transfusion therapy because the anemia has occurred gradually and there has been physiologic compensation. However, occasionally patients experience acute and/or severe anemia and require transfusions for support until other treatment modalities reduce the hemolysis. Transfusion therapy is complicated by the fact that the blood bank may be unable to find any 'compatible' blood. This is because the autoantibody is directed to a product of the Rh locus which is present on the erythrocytes of essentially all potential donors, regardless of Rh subtype. The usual recommendation is for the blood bank to identify the most compatible units of blood of the patient's own major blood group and Rh types. Using this approach, it is unlikely that the donor blood will have a dramatically shortened red blood cell survival.

The indication for transfusion therapy is prevention of any serious complications due to the anemia. These include angina, congestive heart failure and central nervous system symptoms of hypoxia (for example, syncope, lightheadedness, impairment of mental acuity). In addition, if the patient is experiencing blood loss, transfusion is required. The slow infusion of 1–2 units of packed red cells usually improves the clinical status of the patient. Elderly patients especially need to be monitored for circulatory overload and for transfusion reactions. The latter are unlikely to be serious since hemolysis is usually

extravascular. In the rare patient with little or no response to steroids and a continuing need for transfusions because of serious side-effects of anemia over the first 4–6 days of therapy, an early decision for splenectomy may be necessary.

In cold agglutinin disease it is important to pre-warm all intravenous infusions, including whole blood, to 37°C because a decrease in temperature locally in a vein can enhance the binding of the IgM antibody to red cells and accelerate the hemolytic process. In addition, erythrocyte agglutination in a small blood vessel can result in vascular compromise and ischemia to an extremity.

ANEMIA, DRUG-INDUCED IMMUNE HEMOLYTIC

A H Waters, Department of Haematology, St Bartholomew's Hospital, London, UK

Acquired hemolytic anemias may develop as the result of immunological reactions consequent to the administration of certain drugs. Clinically, they often closely mimic autoimmune hemolytic anemia of 'idiopathic' origin and for this reason a careful enquiry into the taking of drugs is a necessary part of the investigation of any patient suspected of having an immune hemolytic anemia.

It is common experience that a particular drug may cause hemolysis in one patient, thrombocytopenia in another, neutropenia in yet another, and sometimes combinations of these in the one patient. The drug-induced antibodies responsible for these immune cytopenias are cell specific. We are still at a loss to know why a particular drug binds to a particular cell in a particular patient.

Mechanisms of drug-induced immune cell destruction

The basic mechanisms are widely accepted, although some essential details remain hypothetical.

In a unifying concept, the primary immune response is initiated by an interaction between the drug or its metabolites and a component of the blood cell membrane to create a neoantigen (Figure 1). The target orientation of the antibodies covers a spectrum from drug-dependent antibodies, which bind to both the drug and the cell membrane, but not to either separately, to drug-independent autoantibodies for which the greater part of the neoantigen is sufficiently similar to the normal cell membrane to allow binding without the drug being present. Both types of antibody may be present at the same time in some patients.

Drug-dependent immune hemolytic anemias

In these cases the drug is required in the *in vitro* sys-

tem for the antibodies to be detected. The red cells may be damaged in two ways.

1. *Complement-mediated lysis.* A typical history is for hemolysis, which may be severe and intravascular, to follow the readministration of a drug with which the patient has previously been treated, and for the hemolysis to subside when the offending drug has been identified and with-

Figure 1 Mechanisms of drug-induced immune cytopenia. Drug-induced antibodies may react with the drug-receptor complex (drug-dependent antibody) or with the drug receptor alone (drug-independent autoantibody). Both types of antibody may be present at the same time.

drawn. The direct antiglobulin test (DAT) is likely to become strongly positive during the hemolytic phase, the patient's red cells being agglutinated by antibodies to complement and sometimes by anti-immunoglobulin G (IgG).

Drugs that have been shown to cause hemolysis by this mechanism include quinine, quinidine and rifampicin, as well as chlorpropamide, hydrochlorothiazide, nomifensine, phenacetin, salicylazosulfapyridine, the sodium salt of *p*-aminosalicylic acid and stibophen.

2. *Extravascular hemolysis.* This is brought about by IgG antibodies that usually do not activate complement, or if they do, not beyond C3. The direct antiglobulin test will be positive with anti-IgG, and sometimes also with antibodies to complement.

The hemolytic anemia associated with prolonged high-dose penicillin therapy is caused by this mechanism, and other penicillin derivatives, as well as cephalosporins and tetracycline, may cause hemolysis in a similar fashion. Hemolysis ceases when the offending drug has been identified and withdrawn.

Drug-independent autoimmune hemolytic anemias

In these cases the antibody reacts with the red cell in the absence of the drug. The anti-red cell autoantibodies seem to be serologically identical to those of 'idiopathic' warm-type autoimmune hemolytic anemia. The great majority of cases have followed the use of the anti-hypertension drug α -methyldopa (Aldomet). The red cells are coated with IgG and the serum contains autoantibodies which characteristically have Rh specificity.

In patients receiving α -methyldopa the autoantibody is often present (15–20%), but hemolysis is not common (<1%). Studies of reticuloendothelial clearance in patients receiving α -methyldopa suggest that the drug itself may blockade the reticuloendothelial

system in most patients, effectively blocking cell destruction by the autoantibody.

Other drugs that have been reported to act in a similar fashion to α -methyldopa include chlor-diazepoxide (Librium), mefenamic acid (Ponstan), flufenamic acid and indomethacin.

Serological investigation

Typical serological features of the different types of drug-induced hemolytic anemia of immunological origin are summarized in Table 1. The drug may be added directly to the assay system (and included in the wash solution) or the cells may be pretreated with the drug (e.g. penicillin). For some drugs a metabolite and not the native drug is the appropriate antigen for testing; in these cases an *ex vivo* drug antigen may be used, from plasma or urine collected from volunteers or other patients after ingestion of therapeutic doses of the drug.

Review of the table reminds us that drug-induced antibodies may react as autoantibodies, so that positive reactions of serum and eluate with normal red cells do not exclude a drug as an etiologic agent.

Idiosyncrasy of drug-induced cytopenias

As already indicated, the antibody may recognize not only the drug but also a specific cell membrane component. Antibodies from patients with drug-induced thrombocytopenia or neutropenia show restriction, in that they react with variable proportions of normal donor cells exposed to the drug (10–80% in one study). This is not related to HLA or known cell-specific antigens, and family studies suggest that an unidentified polymorphic membrane determinant may be involved as a cell receptor/carrier. Another feature of drug-induced antibodies is their extreme heterogeneity from patient to patient and their individual specificity, reflecting a unique immune response.

ANEMIA, PERNICIOUS

Senga Whittingham, Centre for Molecular Biology and Medicine, Monash University, Clayton, Victoria, Australia

Pernicious anemia is an anemia which occurs in the terminal stages of the chronic destructive autoimmune disease, autoimmune gastritis. The anemia results from the death of parietal cells in the body of the stomach due to an immunologic reaction and in the absence of gastric parietal cells, a blood-sustaining vitamin B₁₂ is no longer transported to its site of absorption.

Thomas Addison is acknowledged as the physician who, in 1849, described the clinical features of the anemia. The term 'pernicious' emphasized the inevitable progress and fatal outcome of the anemia and this description given by Biermer in 1972 has endured despite the knowledge that it is appropriate only to the terminal phase of the disease. The disease is, in fact, autoimmune gastritis for which histologic evidence was documented by Fenwick in 1870. However the importance of the link between the anemia and gastritis was not recognized until many years later.

Treatment played a major role in the eventual understanding of the development of pernicious anemia. The earliest studies were directed towards halting the progress of the anemia, and the prevention of death from the disease. Meals of crude extracts of hog stomach or cooked liver produced a reticulocyte response, indicating that new erythrocytes were made in response to ingestion of such meals. The reason for this became clear when Castle, in the 1950s, showed that the response was dependent on the pres-

ence in food of an extrinsic factor which reacted with intrinsic factor secreted into gastric juice. However, despite intensive treatment, relapses occurred and, in some instances, the anemia became refractory to treatment. The refractory state appeared to be due to the development of an inhibitory factor in the serum because serum mixed with gastric juice inhibited the effectiveness of the gastric juice. Rabbits injected with gastric juice produced antibodies which showed the same inhibitory effect. The essential factor, extrinsic factor, in food was shown to be vitamin B₁₂ and the inhibitory factor in gastric juice (and serum) was autoantibody which reacted with the receptor for vitamin B₁₂ on intrinsic factor. Binding of vitamin B₁₂ to intrinsic factor was inhibited and the inhibition of this normal physiologic process prevented the transportation of vitamin B₁₂ to its site of absorption. Blood cells deprived of their essential building block, vitamin B₁₂, failed to mature and the outcome was the development of a pernicious and progressively fatal anemia.

Clinical and hematologic features of pernicious anemia

The autoimmune processes that finally result in vitamin B₁₂ deficiency may be operative for many years, perhaps 20 years or more, before the gastric parietal cells are functionally exhausted. The patient is usually a middle to older-aged woman of Northern

European origin. She is pale, mentally depressed, physically tired, has abdominal discomfort and may show signs of neurologic degeneration if vitamin B₁₂ deficiency has been prolonged and severe. A film of blood or aspirate of bone marrow will show features of megaloblastic anemia. Her gastric juice is greatly reduced in volume and lacks acid. Her levels of vitamin B₁₂ and pepsinogen 1 are low and there is an abnormally high level of serum gastrin.

These diagnostic criteria for anemia are 'insensitive' as disease markers for autoimmune gastritis because they are not evident until late in disease and therefore identify only a small proportion of patients. The earliest marker indicating the presence of chronic autoimmune gastritis is the gastric parietal cell autoantibody (GPCA), and since it is detectable early in the disease and persists throughout the evolution of the disease, it assumes considerable importance as a marker of the autoimmune process that may terminate in pernicious anemia. GPCA (Figure 1) is detected by immunofluorescence using frozen sections of parietal cell-rich areas of human or rodent stomach, preferable murine rather than rat because human serum may react nonspecifically with rat parietal cells. Over 90% of patients with autoimmune gastritis have GPCA.

Immunology

The gastric autoantigens

The two autoantigens targeted by autoantibodies are components unique to the gastric parietal cell in the

Figure 1 The gastric parietal cell antibody detected by immunofluorescence and illustrated here on murine gastric mucosa reacts with the cytoplasm of gastric parietal cells. Characteristic of the immunofluorescence reaction is the denser staining of the newly formed cells at the base of the mucosa (bottom left) and lighter staining of the mature cells towards the top of the mucosa. Experimental evidence suggests that the autoantigen in the parietal cell is the enzyme H⁺,K⁺-ATPase which is involved in production of acid secreted into the gastric juice.

body of the stomach. The autoantigen with which GPCA reacts is the enzyme H⁺,K⁺-adenosine triphosphatase (H⁺,K⁺-ATPase) which is cell-specific but not species-specific, indicating the importance of the physiologic role of the molecule in the gastric parietal cell. The second autoantigen is a secreted product of the gastric parietal cell, gastric intrinsic factor.

H⁺,K⁺-ATPase Gastric H⁺,K⁺-ATPase is the enzyme responsible for the acidification of gastric juice and is otherwise known as the proton pump. It belongs to a family of ion-motive-P-type ATPases which include Na⁺,K⁺-ATPase and Ca²⁺-ATPase which have highly conserved catalytic α subunits that are phosphorylated during their reaction cycles. Only H⁺,K⁺-ATPase and Na⁺,K⁺-ATPase have a β subunit which includes a heavily glycosylated 35 kDa core protein. The gastric enzyme, which is heterodimeric, is located on intracellular and apical membranes of the gastric parietal cells. Autoantigenic determinants of H⁺,K⁺-ATPase are located on both the catalytic 100 kDa (α) and the glycosylated 60–90 kDa (β) subunits.

Gastric intrinsic factor Gastric intrinsic factor, the other major autoantigen in autoimmune gastritis, is a glycoprotein with a molecular weight of 44 kDa. Each molecule has the capacity to bind to one molecule of vitamin B₁₂ and of its two autoantigenic determinants, one is at the binding site for vitamin B₁₂ and the other is on a part of the molecule remote from this site.

The gastric autoantibodies

The major autoantibodies implicated in autoimmune gastritis are GPCA and the two antibodies that react with gastric intrinsic factor. Since H⁺,K⁺-ATPase is unique to the gastric parietal cell and is responsible for acid production, the inhibitory effect of the immune response on anti-H⁺,K⁺-ATPase accounts for hypochlorhydria. The scenario for the effect of autoantibodies is as follows.

Upon reaching the stomach after ingestion, vitamin B₁₂ in the acid medium of gastric juice is freed from protein to bind to intrinsic factor. When acid secretion is inhibited by anti-H⁺,K⁺-ATPase the amount of vitamin B₁₂ free to bind to intrinsic factor is greatly reduced and if the vitamin B₁₂ site on intrinsic factor is blocked by antibody little, if any, will bind to intrinsic factor. The result is malabsorption of vitamin B₁₂ and as the autoimmune gastritis progresses the stores of vitamin B₁₂ dwindle to levels that can no longer sustain blood and nervous system metabolism. The patient becomes anemic and neurologic complications follow (Figure 2).

Figure 2 The end-stage of autoimmune gastritis is gastric atrophy. This results in malabsorption of vitamin B₁₂ and pernicious anemia with neurologic complications when vitamin B₁₂ deficiency is severe. The histologic appearance of autoimmune gastritis is that of chronic inflammation.

In addition to autoantibodies to gastric antigens, patients with pernicious anemia have a substantially higher than normal frequency of antibodies to components of cells which are targets in diseases associated with autoimmune gastritis (Table 1). These autoantibodies include those reactive with thyroid peroxidase, thyroglobulin, pancreatic islet cells, adrenal cortical cells and ovarian cells and indicate the patient either has or is predisposed to the associated disease in which these antibodies occur.

Cell-mediated immunity to gastric antigens

The contribution of cell-mediated immunity to the gastric lesion in the body of the stomach is poorly understood. Increased numbers of T lymphocytes of the CD4 and CD8 lineages as well as a greatly increased number of B cells have been observed in

the gastric lesion. It is presumed that T cells provide help required for the production of the gastric autoantibodies because these antibodies are predominantly of the immunoglobulin G (IgG) isotype, and that they also participate in the destruction of the gastric cells. One elegant study by electron microscopy showed T lymphocytes lined up against the membranes of gastric parietal cells and chief cells as if poised to destroy these cells.

Both gastric parietal cells and chief cells become greatly reduced in numbers as the inflammation progresses. Why there is accompanying loss of chief cells is, as yet, an enigma because the autoimmune attack is not thought to be directed at chief cells. Levels of serum gastrin are high probably because gastrin production by antral cells is under the control of gastric acidity and when acid is insufficient due to the absence of the parietal cells an essential feedback mechanism fails and levels of gastrin rise.

Gastritis

The autoimmune reaction is confined to the body of the stomach. The end-result is gastric atrophy but the rate at which the lesion progresses to this stage cannot be predicted in any individual patient. Some patients may maintain adequate vitamin B₁₂ absorption for 20 years or more while others progress rapidly to atrophy.

The recognition of the 'pernicious anemia type' of gastritis was first made by Strickland and Mackay in 1973 who proposed a classification based on differences in the histologic findings in the body and antrum of the stomach. Type A gastritis was the 'pernicious anemia type' in which the immune reaction progressed until the glandular destruction was total and the mucosa atrophic. It was confined to the body of the stomach, and was associated with GPCA and high levels of serum gastrin. Type B gastritis was the 'simple' gastritis now mainly attributed to infection with *Helicobacter pylori* in which glandular destruction did not progress to total atrophy of the glands of both body and antrum, and was not associated

Table 1 Autoantibodies to nongastric components in pernicious anemia

Autoantibodies to:	Frequency	Disease association
Thyroid cells	30%	Hashimoto's thyroiditis
Thyroid peroxidase		Graves' disease
Thyroid hormone receptor		Atrophic hypothyroidism
Thyroglobulin		
Pancreatic islet cells	5%	Insulin-dependent diabetes mellitus
Adrenal cortical cells	5%	Primary Addison disease of the adrenal gland
Ovarian cells	Rare	Primary ovarian failure associated with Addison's disease
Neuromuscular junction	Rare	Lambert-Eaton syndrome

with GPCA or abnormally high levels of gastrin. Regeneration of gastric parietal cells, improved gastric function, and hematologic remission occurred after treatment with immunomodulating drugs such as the corticosteroid drugs and azathioprine, further suggesting that type A gastritis was immunologically mediated.

Animal models of autoimmune gastritis

Spontaneously occurring autoimmune gastritis

There is no animal model in which the primary disease is autoimmune gastritis although atypical forms of autoimmune gastritis are present in a proportion of animals whose primary autoimmune disease is one of the diseases associated with autoimmune gastritis. For example BB/W rats whose primary disease is insulin-dependent diabetes mellitus may have gastric parietal cell antibodies and histologic evidence of mild to moderate gastritis. However they have no reduction in acid secretion or fall in level of vitamin B₁₂. Another example, the obese strain chicken model of Hashimoto's thyroiditis may also have gastric parietal cell antibodies but the chicken provides a poor model of the human gastritis.

Experimentally induced autoimmune gastritis

Attempts to develop models of autoimmune gastritis in rhesus monkeys, dogs and rats by injecting gastric mucosa with immunologic adjuvants have met with only partial success and when inflammatory gastritis is induced it does not persist and progress like the human disease. The model that best mirrors the human disease is that which develops in BALB/c mice following four injections of murine H⁺,K⁺-ATPase emulsified in Freund's complete adjuvant. Although the lesion is reversible after cessation of immunization, the response to immunization is a florid gastritis with destruction of the parietal and chief cells and development of GPCA. An alternative model in the BALB/c mouse is the gastritis which follows thymectomy performed within 2–4 days of birth of the BALB/c mouse or thymectomy and a single dose of cyclophosphamide in the adult mouse. Two criteria are important in the development of these thymectomized models. One is the timing of thymectomy in the neonate which must be performed within 2–4 days of birth and the second is the need for combined treatment in the adult because neither thymectomy alone nor cyclophosphamide alone will result in gastritis.

Analysis of the cells in the early gastric lesion in the BALB/c models shows B cells, CD4 T cells and macrophages predominate. Transfer of splenic lym-

phocytes from affected animals to immunocompromised murine hosts results in autoimmune gastritis in the hosts, the cell responsible for the transfer being the CD4 T cell and its target the β subunit of gastric H⁺,K⁺-ATPase.

Inheritance

Three pieces of evidence converge to suggest that there is a genetic predisposition to pernicious anemia: the high prevalence of pernicious anemia in some racial groups, the high frequency of pernicious anemia in families within those racial groups, and the association of particular genetic markers among patients with pernicious anemia.

Pernicious anemia is predominantly a disease of people of Northern European origin. It is rare among Southern Europeans, Asians, Latin-Americans, and African and American Blacks and when it occurs in African and American Blacks it does so at an earlier age than it does in White Europeans and there is a higher frequency of antibodies to gastric intrinsic factor.

Multiple cases of pernicious anemia have been reported in families, often for several generations, and this frequency may be as much as 20 times greater than in the normal population. There is a raised but not absolute concordance of pernicious anemia in monozygotic twins and there are intrafamilial aggregations of the autoimmune diseases associated with pernicious anemia, namely the thyroid autoimmune diseases, insulin-dependent diabetes mellitus and primary Addison's disease of the adrenal gland which may be expressed as frank or subclinical disease marked by the presence of autoantibodies specific to these diseases. The prevalence of gastric parietal cell antibodies in first-degree relatives of patients with pernicious anemia is 20% which is three times higher than that found in normal controls and the frequency of autoantibodies to thyroid, pancreatic islet cells and adrenal cortical cells is also higher among relatives.

The higher frequency of gastric autoantibodies among relatives of patients with pernicious anemia is also in keeping with the high frequency of type A gastritis among relatives. Studies by Varis and colleagues on a large population of patients with pernicious anemia and their relatives in Finland showed that the prevalence of autoimmune gastritis was 13% higher in relatives than in controls. This familial aggregation of autoimmune gastritis was attributed to a genetic effect rather than an environmental factor. A delay in the onset of gastritis in males suggested that 'maleness' may have a protective effect.

Blood group A and blue eyes are phenotypes

which are common among Northern Europeans with pernicious anemia. Female gender on this phenotypic background potentiates predisposition to the autoimmune gastritis. Various HLA antigens have been associated with pernicious anemia although these associations are generally weak and have not been corroborated in all studies. Evidence for genetic polymorphism has been observed: HLA-B7, -B12, DR2 and DR2/4 heterozygosity has been shown to be increased in frequency in patients with pernicious anemia alone, and HLA-B8, -B18, -Bw15, DR3 and DR3/4 heterozygosity has been demonstrated in patients with pernicious anemia with an associated autoimmune endocrine disease. HLA-B12 has associated with severe vitamin B₁₂ malabsorption and neuromyelopathy, and an increased frequency of Dw2 has been reported in patients with antibodies to gastric intrinsic factor.

Treatment

The standard treatment is administration of vitamin B₁₂ by regular injection to replace that no longer absorbed from food. Being an immune-mediated disease, autoimmune gastritis is also ameliorated by immunomodulating drugs. However serious side-effects may result from treatment with such drugs and this is not the treatment of choice. If untreated, the outcome of the gastritis and vitamin B₁₂ malabsorption is a fatal anemia with neurologic complications.

Conclusion

Pernicious anemia is the result of functional failure

of the gastric parietal cell, and the gastritis associated with it fulfils the criteria for an autoimmune disease. Like most human autoimmune diseases, autoimmune gastritis predominates in women. It is associated with autoantibodies which react with the highly conserved and functionally important molecules, gastric H⁺,K⁺-ATPase and gastric intrinsic factor. There is a genetic predisposition to its development and this is potentiated in the female. It is associated with other well-defined organ-specific autoimmune diseases affecting endocrine glands. How these data are related to the cause, potentiation and maintenance of the gastritis remains unresolved.

ANERGY, B CELL

David M Tarlinton, The Walter and Eliza Hall Institute of Medical Research, Royal Melbourne Hospital, Victoria, Australia

Generation of immunological diversity and the need for tolerance

The adaptive immune system, comprising B and T lymphocytes, functions by the clonal response of those lymphocytes to foreign antigen. Each lymphocyte recognizes a single antigen, and the existence of a particular specificity among a population of lymphocytes does not depend on the prior exposure of the animal to that antigen. That is, the introduction of an antigen does not induce the appearance of lymphocytes specific for that antigen; the cells already

exist. What antigen does is to expand selectively those lymphocyte clones which recognize the antigen. This is the basis of the clonal selection theory formulated by Burnet. Defense against a potentially infinite number of foreign antigens requires the immune system to be able to generate an infinite number of specificities, each borne on a unique lymphocyte clone. The immune system can achieve a spectacular level of diversity among the antigen receptors of B and T lymphocytes by using the random association of gene segments to create the final receptor gene products during lymphocyte develop-

ment. Because the selection of individual gene segments is random, the range of specificities embodied in the final receptor molecules is also random. Some lymphocytes will develop expressing receptors which recognize self antigens, while others will be specific for as yet unencountered foreign antigens. The problem for the immune system is how to prevent the self reactive lymphocytes from responding if and when they encounter their cognate self antigen, while allowing the remainder to survive. The means by which the body silences self reactive lymphocytes is called tolerance. Once the requirement for immunological tolerance had been recognized, it was proposed that its imposition was restricted to the early or neonatal stage of life. This model was subsequently modified by Lederberg to one in which each lymphocyte went through a tolerance-sensitive stage during its development. Encountering antigen during this phase resulted in the lymphocyte being permanently disabled. If, however, an antigen was encountered after this developmental stage, then the lymphocyte would be activated and initiate an immune response. Thus while some lymphocytes specific for a foreign antigen may be in a tolerance-sensitive state when they first encounter antigen, other lymphocytes with the same specificity which developed prior to the introduction of the antigen and which are therefore not tolerant, would respond. Self antigens, on the other hand, would always be present and thus able to tolerize each developing lymphocyte.

Early models of tolerance induction invariably invoked clonal deletion as the means by which self reactive cells were rendered tolerant. That is, self reactive lymphocytes were killed by interaction with self antigen. Numerous experiments dating from the 1970s, however, suggested that not all self reactive B cells were deleted. After Naor and Sulitzeanu described the enumeration of antigen-specific lymphocytes by their ability to bind radioactively labeled antigen, others used the same technique to determine whether antigen-specific B cells persisted in tolerant animals. In some instances a reduction in the number of such B cells was observed, while in others no change was seen, suggesting that B cell tolerance was not obligatorily associated with deletion. Using this technique it was possible to demonstrate in apparently healthy animals the presence of lymphocytes which could bind self antigens such as thyroglobulin. Yet other groups showed that polyclonal B cell activators such as lipopolysaccharide could induce the production of autoantibodies from animals with no overt signs of autoimmunity. The overall effect of these and other experiments was to call into question

the exclusive role of clonal deletion in establishing and maintaining immunological tolerance.

Clonal anergy

Experiments pioneered by Nossal and Pike in the 1980s led to the enunciation of clonal anergy as an alternative mode of B cell tolerance induction. In the original experiments these workers reported that while both high and low doses of antigen could induce tolerance, only the high doses resulted in deletion. Low doses of antigen tolerized the animals such that they were subsequently unable to respond to immunogenic forms of the same antigen, despite the persistence of antigen-specific B cells. Data supporting clonal anergy as a means of tolerizing T cells subsequently emerged. Progress in resolving the relative importance of clonal deletion and anergy in maintaining immunological tolerance was hindered by the difficulty in detecting and enumerating antigen-specific lymphocytes in normal animals and in quantifying changes to this population upon the induction of tolerance. Subsequent advances in this field have depended on the use of immunoglobulin transgenic animals.

Transgenic models of B cell tolerance

Immunoglobulin transgenic mice are derived by the introduction of genes encoding functional immunoglobulin heavy and light chains into a zygote. Although every cell in the resultant transgenic mouse carries the introduced genes, expression will only occur in those cells containing the appropriate transcription elements. In the case of immunoglobulin genes, this means B cells and occasionally T cells. Expression of the transgenic immunoglobulin chains in early B cell precursors inhibits the rearrangement of the endogenous immunoglobulin genes and therefore results in an animal in which essentially every B cell develops with the same antigen specificity. If the antigen for which the immunoglobulin transgenes are specific is present in the same animal, then all the B cells will be autoreactive. A number of model systems have been developed employing this approach. In various forms the transgenic B cells are specific for DNA, for major histocompatibility complex (MHC) class I antigens, for mouse red blood cells and, in a particularly flexible model, the B cells are specific for hen-egg lysozyme (HEL). While HEL is obviously not a mouse self antigen, mice transgenic for HEL have been made and, when crossed with the immunoglobulin transgenic mice, create a situation of self reactivity. An advantage of this system has been that the form in which the HEL is expressed

can be altered by changing aspects of the transgene, thereby allowing different forms of B cell tolerance to be studied. Using these transgenic models, it was quickly revealed that if the self antigen was a membrane-bound protein expressed on cells present in the bone marrow, blood or peripheral lymphoid organs, then self reactive B cells were deleted. This deletion was rapid, efficient and required a surprisingly low affinity for the antigen. In situations in which the self antigen was not membrane bound, but rather existed as a serum protein to which the B cells were chronically exposed, then the self reactive B cells were not rapidly deleted, but rather rendered anergic. Analysis of transgenic self reactive systems that promote B cell anergy rather than deletion has revealed some of the cellular and molecular changes that characterize this state of immunological unresponsiveness.

Anergic B cells

The biology of anergic B cells differs from that of nonself reactive B cells in several respects, including the level of expression and functional capability of surface immunoglobulin, activation of helper T cells, lifespan and migration within the lymphoid system. Mature B cells ordinarily express both immunoglobulin M (IgM) and IgD on the cell surface at relatively uniform levels. Anergic B cells express IgD at levels equal to that of nonself reactive (or normal) B cells, but they downregulate IgM by between 5- and 50-fold. The downregulation of IgM is associated with an inhibition in signaling such that phosphorylation of critical signal transduction molecules associated with surface immunoglobulin is diminished. Molecules such as the syk tyrosine kinase and the immunoglobulin coreceptors $Ig\alpha$ and $Ig\beta$ are underphosphorylated in anergic B cells following receptor stimulation. A further consequence of this inhibition in signaling is the fact that receptor stimulation of anergic B cells does not result in the release of intracellular calcium, a critical component in the pathway of B cell activation.

While the changes which are intrinsic to the B cell clearly inhibit the ability of the anergic B cell to respond to subsequent exposure to its cognate antigen, such a state of unresponsiveness can be reversed by signaling through CD40. In certain situations in which anergic B cells are exposed to either CD40 ligand or antibodies specific for CD40 in the presence of the cytokine interleukin 4 (IL-4), the B cells proliferate and differentiate into antibody-secreting plasma cells. This experimental result, however, does not extend to the anergic B cell being able to solicit help from antigen-specific T cells. B cells encountering their cognate antigen in a form which cross-

links surface immunoglobulin will not only process and present the antigen to T cells on MHC class II, but will also upregulate the costimulatory B7 molecules. These molecules are critical for the activation of helper T cells which induces expression of CD40 ligand on T cells, which in turn is critical for the final differentiation of the B cell into an antibody secreting cell. Anergic B cells fail to significantly upregulate B7-2 in response to receptor cross-linking, meaning that they are unable to activate T cell help. This further diminishes the possibility of anergic B cells responding to self antigen.

Self reactive B cells, however, never constitute the entire output of the lymphoid system – they exist among cells which show no self reactivity. In this respect the transgenic models described above, while useful, are somewhat less than ideal. More realistic situations have been developed in which only a fraction of the B cells are specific for a self antigen and their behaviour in relation to their nonself reactive peers can be assessed. Such studies have been conducted by two groups, one being that of Cyster and Goodnow and the second Fulcher and Basten. These experiments have revealed that anergic B cells show a distinct pattern of recirculation in the lymphoid organs relative to nonself reactive B cells. Normally, mature B cells leave the blood, migrate through the T cell areas of the lymphoid organs and enter the B cell follicles. From here they enter the lymphatic circulation which eventually returns them to the blood. Self reactive B cells in the presence of their cognate self antigen enter the secondary lymphoid organs but are unable to enter the B cell follicles. Instead they accumulate at the border of the B and T cell areas of the spleen where they die within a few days in the absence of T cell help. If T cell help is available then the B cells become activated and give rise to structures characteristic of an immune response, namely antibody-forming cells and germinal centers. Thus tolerance of the immune system is a cooperative event, requiring both tolerance in the T and B cell compartments. The failure of self reactive B cells to enter the follicles has been the subject of two interpretations. In one case, Cyster and coworkers suggest that self reactive B cells are unable to compete effectively for a homing signal emanating from the follicle and therefore are excluded. In order for B cells to have a long life they need to have access to survival factors in the follicle, and thus excluded self reactive B cells die quite rapidly. Fulcher and Basten, on the other hand, suggest that localization of the cells in the T cell area of the spleen is a consequence of receptor stimulation and is indicative of the B cells searching for T cell help. If that help is not forthcoming, as would normally be the case for

a self antigen, then the B cells rapidly die. Furthermore, this group argues that the critical factor determining whether an individual B cell is able to enter the follicles or not is the level of receptor engagement. If the concentration of self antigen is low, then the B cell is able to ignore the signal and behave like a nonself reactive cell. Once the concentration is above some threshold level, however, then the lymphocyte changes its trafficking pattern and has a reduced lifespan in the absence of T cell help.

Breaking anergy

B cells made anergic by chronic exposure to a self antigen are able to be activated in some instances. As indicated above, stimulation of anergic B cells through the CD40 molecule in the presence of IL-4 is able to induce proliferation and differentiation of the B cell. Similarly, extensive cross-linking of surface immunoglobulin on the B cell is able to activate the cell. This can be achieved, for example, when a B cell chronically exposed to soluble monomeric self antigen encounters the same antigen in a highly multimerized form such as a cell protein. In this case, the B cell will proliferate and differentiate into an antibody-forming cell in the presence of the appropriate cofactors. This reversal of anergy is dependent on the strength of the receptor signal. In the presence of soluble self antigen, anergic B cells are killed by antigen specific nontolerant helper T cells. This death is dependent on anergic B cells expressing the apoptosis-inducing molecule Fas and the helper T cells expressing its ligand. This lethal embrace can be transformed into a stimulatory one if the antigen receptor stimulation given to the B cell is sufficiently strong.

Why is anergy reversible?

Clonal anergy, defined as the presence of antigen-specific B cells in an unresponsive state, can be achieved by a number of mechanisms. Some involve modulation of the signaling of the B cell itself, while others alter the ability of these B cells to solicit and respond to T cell help. Still other mechanisms alter the location of anergic B cells in the lymphoid system and their lifespan. Why are so many tolerance mech-

anisms employed when it would be simpler to delete any lymphocyte which showed traces of self reactivity? Several explanations have been put forward to answer this question, most cogently by Goodnow. First, not all self antigens will be present in bone marrow when the B cells are developing and sensitive to tolerance induction. Second, if all B cells which show any degree of binding to self antigens were to be deleted, it is questionable that the lymphoid system could generate a sufficient number of cells to counter the infectious agents animals are exposed to. That is, anergy may be a means by which the immune system is able to silence potentially harmful B cell clones and yet have B cells survive long enough to be exported to the peripheral lymphoid organs. In these locations it is possible that the anergic B cells may encounter a foreign antigen to which they have a higher affinity than that with which they recognize the self antigen. If this were the case, then the anergic B cell could be activated and participate in a protective immune response. The anergic B cells would quickly die, however, if no such foreign antigen existed at the time it reached the periphery. This may also account for the reversibility of B cell anergy.

In 1908 C. Von Pirquet first used the term anergy (from the Greek meaning without work or not working) to describe the loss of response to a tuberculin skin test in patients infected with the measles virus. Since then this type of phenomenon has been described for delayed-type hypersensitivity responses to a variety of antigens during the course of a number of different infectious diseases. It appears to be a nonspecific suppression of the T cell response which reverses when the infectious agent is cleared. In 1980 Nossal and Pike borrowed the term and used it to describe the state of antigen-binding B cells isolated from an adult mouse that had been made unresponsive by injection of a tolerogenic dose of antigen. The B cells failed to differentiate into immunoglobulin secreting cells when restimulated *in vitro* with either antigen or the mitogen lipopolysaccharide. They called this form of unresponsiveness 'clonal anergy', to denote that the unresponsiveness was antigen specific. The tolerogenic regimen used in these experiments was derived from the earlier work of Dresser, who demonstrated that intravenous injection of deaggregated proteins in the absence of an adjuvant would induce a subsequent state of unresponsiveness to that antigen. In contrast, if the same preparation of antigen was given with Freund's complete adjuvant as a costimulator, it was immunogenic. This work eventually gave rise to the concept that antigen stimulation of a lymphocyte in the absence of costimulation was tolerogenic. When a similar phenomenon was discovered for cloned T cells in tissue culture, the term clonal anergy was extended to this population as well. In this case the unresponsiveness was a failure of the T cells to proliferate on rechallenge with antigen presented by professional antigen-presenting cells (APCs). It is this last category of the use of the term clonal anergy to which this entry is confined.

The induction of T cell clonal anergy in the mouse was first achieved by stimulating cultured lymphocyte clones with peptide antigens and chemically fixed APCs. Induction of this same state with purified major histocompatibility complex (MHC) class II molecules in planar membranes made it clear that T cell receptor (TCR) occupancy by peptide – MHC complexes was all that was necessary for anergy to occur. Other forms of pure TCR engagement, such as concanavalin A crosslinking in the absence of

APCs or plate-bound anti-CD3 monoclonal antibody, also induced clonal anergy, although significant amounts of cell death were observed as well. Anergy induction was prevented by addition of APCs, giving support to the paradigm that signal 1 (the antigen-specific signal) alone was inhibitory, whereas signal 1 plus signal 2 (costimulation) was stimulatory. The nature of the costimulatory signal was subsequently shown to be engagement of the T cell CD28 molecule by its ligands CD80 and CD86 on the APC. The requirement for APC activation in order to express CD80/86 explains why the original chemical fixation experiments prevented costimulation.

Anergic T cell clones have a very distinct pattern of partial inactivation. Proliferation is prevented on restimulation by a number of mechanisms. First and foremost, interleukin 2 (IL-2) production is inhibited by 20–50 fold. This block is at the level of transcription and appears to involve interference with signal transduction through the p21^{ras}/MAP kinase pathway. The latter prevents activation of the transcription factor AP-1 which is required for IL-2 gene transcription. Overinduction of the IL-2 transcriptional repressor, Nil-2a, has also been reported in anergic T cells. Production of other cytokines is inhibited, but to varying degrees. IL-3 and tumor necrosis factor α production are inhibited about tenfold. In contrast, IL-4 and interferon γ production are only reduced slightly. Interestingly, in those clones capable of using IL-4 as a growth factor, anergy induction blocks only the ability of the cells to respond to IL-4. Similarly the augmentation of TCR-induced proliferation by IL-12 is inhibited. Finally, expression of CD40 ligand, which is required for T cell mediated, B cell proliferation, is inhibited. The overall pattern suggests that anergy is a growth arrest state designed to reduce proliferation in the T cell immune response.

Costimulation given within 2 hours of TCR occupancy blocks the induction of anergy. This is due to an increase in IL-2 production mediated by a CD28-induced augmentation of IL-2 mRNA stability and an increase in the activity of Jun N-terminal kinase (JNK), which enhances IL-2 gene transcription. The IL-2 produced inhibits anergy by two mechanisms. One is by activation of Janus kinase (JAK)3 via stimulation through the common γ chain of the IL-2 receptor. The other is by driving the cell into

cycle. The division process antagonizes and even reverses the block in the Ras/MAP kinase pathway by an as yet unknown mechanism.

Anergy can also be induced in murine T cell clones by stimulating them with altered peptide ligands. In this case costimulation is normal, but signal transduction through the TCR is suboptimal. This partial signaling possibly results in the production of the inhibitor of the Ras/MAP kinase pathway, but is not sufficient to produce IL-2. As a consequence, the small production of inhibitor is unopposed and the cell becomes anergic. Human T cell clones can also be induced into an unresponsive state by exposure to high concentrations of normal peptide ligands. In this case too, the presence or absence of costimulation makes no difference. A biochemical analysis, however, suggests that the unresponsiveness is mediated by a different mechanism. Here signaling through the calcium/calcineurin pathway is impaired, while the MAP kinase pathway is normal. A similar biochemical block can be observed in mouse cells, but only after they are stimulated through the IL-2 receptor. The murine block, however, is transient, and the cells return to their normal responsiveness in 5–7 days. In order to distinguish the state of unresponsiveness in human clones stimulated with high concentrations of peptide from anergy induced in human and mouse clones in the absence of costimulation, it has been proposed that the latter be called Ras-blocked anergy and the former calcium-blocked anergy.

The *in vitro* demonstration of T cell anergy led to a major effort to identify this state *in vivo*. Two systems have been described which look as though they represent this phenomenon. The first is induced with superantigens such as staphylococcal enterotoxin B (SEB) and minor lymphocyte stimulating (Mls) antigen. In this case subsets of T cells expressing particular V_{β} receptors expand in response to the superantigen stimulus. Several days later many of these cells die, but a small cohort remains and these residual cells are often unresponsive to restimulation with either the superantigen or an antibody against the V_{β} receptor. An analysis of the biochemical events taking place in this population during restimulation revealed a profile similar to that seen in anergic T cell clones. Interestingly the cells *in vivo* showed a block in IL-2 receptor signaling as well as one in IL-2 production. Furthermore, multiple injections of the superantigen seemed to produce a more profound state of anergy in which signaling through the Ras/MAP kinase pathway was blocked to the point of impairing activation of the NF κ B and NF-AT transcription factors in addition to AP-1. A recent report has suggested that this deeper state of

anergy can also be achieved *in vitro* if the T cell clones are exposed to IL-10 during their stimulation through the T cell receptor. The molecular mechanism for this IL-10 enhancement is not known.

The second *in vivo* system in which anergy has been identified involves TCR transgenic mice. CD4 cells from such animals have been transferred to normal recipients and challenged with antigen intraperitoneally in incomplete Freund's adjuvant. Cells recovered from the lymph nodes failed to proliferate *in vitro* when rechallenged with antigen. In a second model, H-Y specific, TCR transgenic, CD8 cells, when transferred into male nude mice, responded in an analogous way to that seen for normal T cells stimulated with superantigens. After an initial expansion and death phase the remaining cells were unresponsive to restimulation with either the antigen or an anti-TCR antibody. To date, the biochemical state of the unresponsive cells has not been examined in either transgenic model. Hence at this time one cannot be certain that the state is the same as that observed in T cell anergy studied *in vitro*.

Given the existence of anergic T cells *in vivo*, one can now ask what their biological function is. No consensus exists on this point. It was originally thought that anergy played some role in self tolerance. Naive T cells make only IL-2 following T cell activation and it was postulated that anergy induction would block this response, thus preventing the T cell from expanding and differentiating into an effector cell. At this point, however, there is no definitive evidence that naive T cells *in vivo* are turned off when given signal 1 in the absence of signal 2. Some experiments suggest that instead the cells may differentiate into T_H2 cells. Anergy and T_H2 differentiation can be distinguished by their responsiveness to IL-4. Anergic T cells cannot proliferate in response to IL-4, whereas T_H2 cells can. So far no investigation has clearly made this distinction. Another possible scenario for anergic T cells *in vivo* is that they are on their way to die. The biochemical events seen inside the T cell during and after anergy induction are not those associated with apoptosis; however, Fas ligand is upregulated *in vitro* and could be used in a subsequent encounter with antigen to mediate cell death. On the other hand, transfer of CD8 TCR transgenic cells into female nude recipients suggests that the cells do not die and that they can actually spontaneously come out of the anergic state in the absence of antigen. Anergy can also be reversed *in vitro* by stimulating the T cell clones with IL-2. Whether this reversibility would provide a useful mechanism for transiently recruiting autoreactive clones for use in an ongoing immune response to foreign antigens remains an intriguing possibility.

ANNEXINS (LIPOCORTINS)

Fusao Hirata, Departments of Pharmaceutical Science, Pharmacology & Institute of Chemical Toxicology, Wayne State University, Michigan, USA

The annexin (lipocortin) family of proteins possess a highly conserved core region, consisting of four or eight repeats of approximately 70 amino acid residues, and a highly variable N-terminal region. The core region mediates Ca²⁺-dependent binding to phospholipid membranes and forms a Ca²⁺ channel-like structure. The physical and structural properties of annexin proteins suggest that they regulate multiple aspects of cell membrane function, including involvement in membrane trafficking, signal transduction and cell–matrix interactions. Some of their actions are akin to those of glucocorticoids, including anti-inflammatory, anti-edema and immunosuppressive effects.

Historical background

Glucocorticoids are widely used as one of the most efficacious medicines against various inflammatory and immunological diseases such as rheumatoid arthritis, systemic lupus erythematosus and bronchial asthma. Their anti-inflammatory action is mediated by inhibition of arachidonic acid release, a precursor of prostaglandins (PGs), hydroxyeicosatetraenoic acids (HETEs) and leukotrienes (LTs). Phospholipase A₂ (PLA₂) and alkylphospholipids, a precursor of platelet-activating factor (PAF), in biomembranes have been considered as the key enzyme and the major source of arachidonic acid, respectively. Anti-inflammatory steroids also inhibit the forma-

tion of both PAF and its inactive lyso-form (deacylated molecule). Since most of the anti-inflammatory actions of glucocorticoids are inhibited *in vivo* and *in vitro* by inhibitors of protein synthesis as well as mRNA synthesis, it was proposed that the anti-inflammatory action of glucocorticoids is partly, if not exclusively, mediated through the induced synthesis of PLA₂ inhibitory protein(s).

Between 1980 and 1984, attempts were made by several groups to isolate a protein 1) whose synthesis is induced by glucocorticoids, 2) that inhibits the activity of PLA₂ *in vitro* and *in vivo*, and 3) that displays an anti-inflammatory action like glucocorticoids. Several different proteins that inhibit PLA₂ *in vitro* were identified and partially purified. These included 'lipomodulin' from rabbit neutrophils (molecular weight = 40 kDa), 'renocortin' from rat kidney cells (molecular weight = 30 kDa) and 'macrocortin' from rat macrophages (molecular weight = 15 kDa). Among these proteins, lipomodulin was best characterized: a possibly glycosylated protein with an apparent molecular weight of 40 kDa and a pI value of 9.0. This protein can bind 2 mol of Ca²⁺ mol⁻¹ protein, and the concentration of Ca²⁺ required for half maximal binding is approximately 1 μM. It was proposed that this protein suppresses PLA₂ activity by forming a complex with PLA₂ at the Ca²⁺-binding site(s). Furthermore, various protein kinases including protein kinase C and tyrosine

protein kinase, can phosphorylate lipomodulin to modify its function and structure as detected by the inhibitory activity against PLA₂ and the susceptibility to proteases.

Despite differences in their chemical properties, all proteins isolated as second messengers of glucocorticoid anti-inflammatory action have similar, if not identical, biological properties: 1) the synthesis of these proteins is induced by glucocorticoids, 2) preparations of these proteins, regardless of their purity, inhibit porcine pancreas and/or snake venom PLA₂ *in vitro*, 3) these protein preparations mimic some actions of glucocorticoids, especially with regard to arachidonic acid release and production of lipid mediators such as prostaglandins, and 4) some monoclonal antibodies raised in one laboratory cross-react with the proteins prepared by the other laboratories. Based upon these findings, it was proposed in 1984 that a family of PLA₂ inhibitory proteins whose syntheses are induced by glucocorticoids be named as *lipo(modulin, macro- or reno-)cortins* (lipocortins). In 1986, the Biogen group purified two proteins from human placenta whose properties are almost identical to those of lipomodulin. They isolated cDNA clones encoding these proteins, and described their chemical natures as follows: 1) their molecular weights are around 36 kDa, 2) they have multiple phosphorylation sites including one for tyrosine protein kinase and a potential glycosylation site, 3) they have four repeats which can bind acidic phospholipids and Ca²⁺, and 4) they inhibit PLA₂ *in vitro*. Interestingly, these cDNA clones were almost identical to the simultaneously discovered cDNAs that encode two of the major substrate proteins (calpactins) for the EGF receptor (tyrosine) kinase.

Diversity in the annexin family

Two protein inhibitors of PLA₂, namely annexin I and II, have the same characteristic structural organization: following unique N-terminal sequences of about 40 amino acid residues, they both are composed of four repeated sequence motifs of 70–80 amino acids, in which a conserved 17 amino acid consensus (Lys-Gly-X-Gly-Thr-Asp-Gln-X-X-Leu-Ile-X-Ile-Leu-Ala-X-Arg) is thought to be important for Ca²⁺-dependent binding to phospholipids. These features have now been identified in sequences of 18 related proteins (Table 1), although annexin VI has 8 repeats instead of the 4 in other annexins. Due to this conserved structure in the C-terminal domain, annexins have a high degree of identity with each other, and maintain around 40–60% amino acid sequence homology. This family of proteins is ubiquitously distributed, being present in lower organisms such as *Drosophila* and plants. They are referred to as annexins since their main property is to 'annex' (bind to) cellular membrane phospholipids in a Ca²⁺-dependent manner. Distinct from the 'EF-hand calcium-binding proteins' such as calmodulin, their intrinsic affinity for Ca²⁺ is generally low (around 0.1–1 mM), and the number of Ca²⁺-binding sites is between 2 and 4. However, the presence of phospholipids increases their affinity for Ca²⁺ up to 100-fold, while Ca²⁺ facilitates their binding to acidic phospholipids (phosphatidic acid > phosphatidylserine > phosphatidylinositol). Although some annexins such as annexin I and II can bind to neutral phospholipids such as phosphatidylethanolamine, their binding to phosphatidylcholine and sphingomyelin, choline lipids, is not detectable. In

Table 1 The annexin (lipocortin) family

	<i>Previous terminology</i>	<i>Biological functions</i>
Annexin I	Calpactin II, Chromobindin 9, GIF, p35	EGF receptor kinase substrate
Annexin II	Calpactin I, Chromobindin 8, p36, PAP-IV, Protein I	Src-kinase substrate
Annexin III	Calcimedlin 35- α , Calphobindin III, PAP-III	
Annexin IV	Calcimedlin 35- β , Calelectrin 32.5K, Chromobindin 4, Endonexin I, PAP-II, PP4-X, Protein II	F-actin-binding protein
Annexin V	Anchorin CII, Calelectrin 35K, Calphobindin I, Calcimedlin 35- γ , Endonexin II, IBC, VAC- α , PAP-I, PP4	Anticoagulant protein
Annexin VI	Calcimedlin 67K, Calelectrin 67K, Calphobindin II, Chromobindin 20, p68, p70, 73K, Protein III, Synhibin	
Annexin VII	Synexin	
Annexin VIII	Vascular anticoagulant (VAC- β)	
Annexin IX	<i>Drosophila melanogaster</i> annexin	
Annexin X	<i>Drosophila melanogaster</i> annexin	
Annexin XI	Calcyclin-associated annexin (CAP)-50	
Annexin XII	<i>Hydra vulgaris</i> annexin	
Annexin XIII	Intestine-specific annexin (ISA)	

contrast to the conserved C-terminal core, each annexin has a unique and extremely variable sequence in the N-terminal domain with the length varying from a few amino acids to 160 amino acids. This domain contains various sites for phosphorylation, glycosylation, acylation and other post-translational modifications. A dimer of annexin II forms a heterotetrameric structure via its N-terminus with a dimer of the p11 protein, a complex which can bind to phosphatidylserine at nanomolar Ca^{2+} concentrations. Therefore, this domain is considered as the regulatory region of the protein for various biological functions.

Results of genomic analysis suggest that annexin genes may be derived from a common ancestor gene, and that the evolution and diversification of the family arose by two consecutive duplications of a DNA sequence encoding a protein resembling a single repeat. The structure of all the annexin genes is well conserved. The 5'-flanking region of annexin genes contains sequences for the binding sites of several transcriptional factors, indicating transcriptional regulation by mitogenic stimulation, steroids and metals, while the 5'-flanking region demonstrates *alu*-like repeats. The presence of potential splice sites and Z-DNA structure in the C-terminal core region produces different isoforms of annexins.

Mechanism of action of annexins

In contrast to the initial proposed mechanism of phospholipase A_2 inhibition whereby annexin I (lipomodulin) was thought to complex with PLA_2 via Ca^{2+} -binding sites, the currently accepted mechanism proposes that annexins bind phospholipids in a Ca^{2+} -dependent manner, thus depleting phospholipid substrates for phospholipase A_2 . Since a certain type of PLA_2 (type II) is released in inflammatory loci, the *in vivo* anti-inflammatory action of annexins is also explained by a hypothetical mechanism in which annexins protect membranes from attack by PLA_2 by binding to membrane phospholipids. Since annexins bind acidic phospholipids such as phosphatidic acid, phosphatidylinositol and phosphatidylserine but not phosphatidylethanolamine or phosphatidylcholine, this interpretation does not explain their specificity for PLA_2 . Lipases such as phospholipase C and phospholipase D, the enzymes that hydrolyze these phospholipids are also potentially inhibited by the same mechanism. Annexins are now found to form complex homo- and heterodimers or tetramers, with annexins or other proteins. The annexin-binding proteins are annexins, collagens, S-100, apolipoproteins, helicase, DNA methyltransferase, protein kinase C, glycerol-3-phos-

phate dehydrogenase, malate dehydrogenase, calyculin, F-actins and PLA_2 . Despite the findings that ratios of annexin I to phospholipid substrate (phosphatidylserine) are an important determinant factor of the *in vitro* inhibition of PLA_2 , the possibility of complex formation is not ruled out. Such protein-protein interaction, whether it be a specific interaction or nonspecific electrostatic interaction, alters the function and stability of these binding proteins. In this sense, annexins have some properties similar to those of 'house-keeping' proteins.

Crystallographic and molecular modeling studies demonstrate that annexins have a calcium channel-like structure. In fact, annexin V and VII are shown to function as voltage-dependent and GTP-sensitive Ca^{2+} channels, respectively. GTP-binding activity has been implicated by a homology between the amino acids 78–236 (the core region) of annexin I and the amino acids 22–171 of *c-K-ras* 2a, a mammalian *ras-onc* gene product which has GTPase activity. It is noteworthy that maize annexin has ATPase activity. It is also speculated that annexins which bind to mitochondrial dehydrogenases such as isocitrate dehydrogenase and malate dehydrogenase may act as Ca^{2+} sensors, since these enzymes are known to be activated by Ca^{2+} without apparent Ca^{2+} -binding sites. Therefore, annexins are distinct from EF-hand and Ca^{2+} -binding proteins such as calmodulin, whose major functions are Ca^{2+} buffering inside cells.

Biological actions and possible physiological roles

Initial efforts have been made to identify and characterize the annexins, particularly annexin I and II, as possible second messengers in response to anti-inflammatory steroids. The observations to date have shown that these recombinant annexins are able to mimic a part, if not all, of the anti-inflammatory action of glucocorticoids, while antibodies against annexins diminish such actions (Table 2). Even some of their fragments containing the N-terminus exhibit similar but weak anti-inflammatory actions. The inflammatory reactions inhibited by annexins and their fragments include not only the release of arachidonate and its metabolites and the formation of PAF but also neutrophil chemotaxis and release of lysozymes. The cytotoxic reaction by cytotoxic T cells and NK cells is also inhibited by both annexins and glucocorticoids. Although the annexin I and II genes contain GRE sequences in their 5'-flanking regions, thus implicating transcriptional regulation by glucocorticoids, induction of the synthesis of annexins by the steroids remains to be determined. Such induc-

tion has been often demonstrated in intact animals and organs, while cultured cells mostly fail to respond to glucocorticoids at either mRNA or protein levels. Since a whole family of annexin proteins which maintain a highly conserved structure in the C-terminal core with each other, occupy approximately 2% of the total cellular proteins, and since their synthesis is dependent on the cell cycle, changes in their mRNA and/or protein levels might be often

underestimated. Alternatively, an unknown mechanism beside the genomic effect of glucocorticoids might be involved in induction of the synthesis of annexin I and II.

Most annexins are localized intracellularly, particularly in the cytosol. However, various stimuli including increased intracellular Ca^{2+} are known to translocate annexins to plasma membranes and other subcellular vesicles including chromaffin granules. Glycosylation and acylation of annexins is thought to be important for such insertion and/or attachment to membranes. Some annexins are known to be extracellularly released. Autoantibodies against annexins in patients with rheumatoid arthritis and systemic lupus erythematosus (SLE) neutralize these annexins, thereby augmenting inflammatory responses in these diseases. Similar observations have been extended to inflammatory diseases such as asthma, psoriasis, and ulcerative colitis. Among these diseases, SLE may involve dysfunction of suppressor T cells in the immune system. During immunoglobulin E (IgE) synthesis *in vitro* annexin I enhances suppressor function by inhibiting the glycosylation of IgE-binding factor.

Similarly, annexins regulate the proliferation-differentiation of suppressor T cells, including cytotoxic T cells. This leads to the suggestion that the immunosuppression of animals bearing tumors can be attributed to monocytes/macrophages in which the synthesis of annexin I is stimulated. Because of the chemical nature of annexin I and II as substrates for tyrosine kinases, including EGF receptor kinase and Src kinases, annexins are associated with the proliferation-differentiation process of many cells other than suppressor T cells (Table 2). Effects of annexins, especially annexin I and II, are similar, if not identical, to those of glucocorticoids. However, the mechanism of action of exogenous annexins cannot be explained by their binding to plasma membrane acidic phospholipids, which are mainly located on the intracellular side of the membranes. In fact, the binding of annexin V is currently used to detect apoptotic cells which have an inverted membrane phospholipid distribution. This suggests that the existence of specific receptors for annexins mediate their actions. Alternatively, annexins may be inserted into membranes to interact with specific enzymes and/or proteins.

Annexin VII has been identified as synexin, a protein which modulates presynaptic functions including the release of neurotransmitters. Similarly, other annexins are reported to participate in exocytosis and endocytosis in a variety of cell functions such as catecholamine release from adrenal chromaffin cells and ACTH secretion from pituitary cells. Such

activity is attributed to the binding of annexins to subcellular vesicle membranes and Ca^{2+} channel and/or sensor action, although the possibility of an interaction between annexins and actin-like cytoskeletal elements, thus changing their bundling, cannot be neglected.

The presence of annexins in nuclei and mitochondria has also been reported. Although annexin II can regulate the replication of DNA in cell-free systems, the detailed mechanism(s) remains to be solved. Since annexin I and II and annexin I-IV have phosphorylation sites for tyrosine protein kinases and protein kinase C (enzymes that regulate the proliferation-differentiation and/or cell cycle of cells) respectively, many reports describe their involvement in the proliferation-differentiation processes of various cells. Such phosphorylation of annexins alters their affinities for Ca^{2+} and phospholipids, and their interactions with other enzymes and/or proteins. A recent report describing the involvement of annexin I in the apoptosis of H_2O_2 -treated thymocytes may also substantiate this contention, because apoptosis, a type of cell death distinct from necrosis, is explained by an abortive cell activation mechanism.

Although the structure and chemical and physical nature of annexins have been extensively studied, the mechanism of most of their biological and physiological actions remain unclear. Considering the unique distribution of certain annexins in specific cell types, it is likely that additional physiological and/or biological roles and mechanisms of actions of the

annexin family of proteins will be explored in the near future.

ANTI-GLOBULIN (COOMBS') TEST

Nevin Hughes-Jones, Molecular Immunopathology Unit, Medical Research Council, Blood Transfusion Centre, Cambridge, UK

The anti-globulin test was developed to detect human blood group immunoglobulin G (IgG) antibodies by agglutination. The negative charge on the surface of red cells prevents them from coming closer than within 20 nm of each other, thus IgG antibodies are unable to cross-link red cells as the Fab arms, even when fully extended, are unable to span this distance. On the other hand, the Fc portion of cell-bound antibody projects outwards sufficiently far to allow an anti-IgG antibody to cross-link between IgG molecules on one cell and those bound to neighboring red cells, thus bringing about agglutination (Figure 1). The development of the test occurred following the discovery of the Rh blood group system in the early 1940s. It was soon realized that there

were two types of antibody involved in this system – those that would directly agglutinate red cells in saline (retrospectively identified as IgM antibodies), and the so-called 'incomplete' or 'blocking' antibodies (now identified as IgG) which would not directly agglutinate but would block the action of the direct agglutinators.

R.R.A. Coombs, A.E. Mourant and R.R. Race, working in Cambridge in the early 1940s, were investigating the various specificities of the antibodies that appeared to be associated with the Rh system. As reported in their publication of 1945, the seminal idea was that red cells sensitized with nonagglutinating anti-Rh antibody 'had absorbed antibody globulin at some points on their surface and that an

Figure 1 Cross-linking of cell bound IgG.

anti-human globulin serum might be expected to react with this in some observable way'. The principle of the test was soon established. In a later publication, they indicated that the test could probably be used to detect any nonagglutinating antibody present in serum (the indirect Coombs' test) by initially absorbing the antibody on to red cells; they also showed that it could also be used to detect antibody on the surface of fetal red cells in hemolytic disease of the newborn (direct Coombs' test).

It is interesting to note that the use of an anti-globulin serum in this way was first described by the Italian physiologist, Moreschi, in 1908. Moreschi showed that if rabbit red cells were reacted with a goat anti-rabbit red cell antibody at too low a concentration to bring about agglutination, they could subsequently be agglutinated by the addition of a goat serum-specific antibody. At that time, human nonagglutinating antibodies were unknown and hence the significance of the reagent was not appreciated and its description was forgotten.

The test is widely used in two areas in clinical immunohematology. First, it is of major importance in blood transfusion in cross-matching for determining compatibility between donor and recipient. Donor red cells are added to the recipient's serum and any nonagglutinating antibody which binds to

the cells can be detected by the addition of the anti-globulin reagent. Second, it is used in the diagnosis of acquired hemolytic anemias for demonstrating the presence of antibodies bound to red cells *in vivo*.

Antiglobulin reagents can be made specific for IgM, IgA and the four subclasses of IgG. The reagents used in cross-matching also contain antibodies specific for the complement component C3, because some antibodies are best detected by testing for the bound complement which is deposited as the result of the antigen-antibody reaction.

ANTI-INFLAMMATORY (NONSTEROIDAL) DRUGS

John L. Wallace, Department of Pharmacology and Therapeutics, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are among the most prescribed drugs and are also widely used in over-the-counter preparations. The first NSAID, aspirin, was first commercialized at the end of the nineteenth century. Since that time, dozens of more potent NSAIDs have been marketed. NSAIDs are used primarily for their anti-inflammatory, analgesic and antipyretic effects, although more recently aspirin has been used increasingly for prevention of myocardial infarction and stroke. While widely used, these drugs are not entirely safe, with well-documented toxicity in the gastrointestinal tract and kidney. In this entry, the mechanisms of action of NSAIDs are reviewed, as are the major adverse effects associated with their use.

NSAIDs and prostaglandin synthesis

NSAIDs fall into a number of different chemical classes, but despite structural heterogeneity, they share activity, toxicity and most probably, mechanism of action (Table 1). While some NSAIDs may have additional activities which contribute to their anti-inflammatory action, it is the ability of all NSAIDs to inhibit the enzyme cyclooxygenase (COX) that is the primary mechanism through which these drugs reduce pain, inflammation and fever. Cyclooxygenase catalyzes the conversion of arachidonic acid to prostaglandins G and H. Subsequent

enzymatic and nonenzymatic reactions result in the conversion of these highly unstable prostaglandins to more stable and physiologically important prostanoids, including prostaglandin E₂, prostacyclin (PGI₂) and thromboxane A₂. Arachidonic acid is a 20 carbon, unsaturated fatty acid found in membrane phospholipids. It can be cleaved from these phospholipids through the actions of phospholipase A₂ or phospholipase C, whereupon it can react with cyclooxygenase to form prostanoids. One of the mechanisms through which glucocorticoids reduce inflammation is by inhibiting this phospholipase-mediated liberation of arachidonic acid from membrane phospholipids. Prostaglandins contribute to the inflammatory process primarily by causing relaxation of vascular smooth muscle around arterioles, thereby increasing blood flow. While prostaglandins themselves cause only minor changes in the permeability of blood vessels, the increase in blood flow they produce results in a synergistic increase in plasma exudation (edema formation) caused by other mediators, such as histamine and bradykinin. In doing so, prostaglandins contribute to three of the cardinal signs of inflammation, namely, redness, swelling and heat.

Prostaglandins also contribute to the pain associated with inflammation. Prostaglandins themselves are not particularly potent at inducing a pain response when applied, for example, to the base of a blister in human skin. However, they can produce a state of prolonged hyperalgesia and increase the sensitivity of peripheral pain receptors to chemical and mechanical stimuli. For example, the presence of prostaglandins at a site of inflammation or injury will greatly increase the sensitivity of pain receptors to mediators such as bradykinin and histamine. By inhibiting prostaglandin synthesis, NSAIDs remove this hyperalgesic component of an inflammatory reaction. NSAIDs exert analgesic effects both peripherally and centrally, although it is the peripheral action that predominates.

Prostaglandins also play a key role in the generation of fever. There is strong evidence that prostaglandins are produced in the hypothalamus in response to interleukin 1 (IL-1). These prostaglandins mediate the resetting of temperature-regulating systems in the hypothalamus. Blockade of

Table 1 Chemical classes of NSAIDs and examples

<i>Chemical class</i>	<i>Examples</i>
Salicylic acid derivatives	Aspirin Diflunisal
Propionic acids	Ibuprofen Naproxen Flurbiprofen Ketoprofen
Indole acetic acids	Indomethacin Etodolac Sulindac
Enolic acids	Piroxicam Meloxicam
Heteroaryl acetic acids	Diclofenac Ketorolac
Fenamates	Mefenamic acid

prostaglandin synthesis by NSAIDs results in a blockade of this effect of IL-1 and other pyrogenic substances. Interestingly, acetaminophen (paracetamol) shares this ability to inhibit prostaglandin synthesis in the hypothalamus and therefore reduce fever, but this drug is a poor inhibitor of prostaglandin synthesis in the periphery, so is not an effective anti-inflammatory drug.

Interaction of NSAIDs with cyclooxygenase

The inhibition of COX activity by NSAIDs occurs in two main ways. Most NSAIDs inhibit this enzyme by binding in a reversible manner to a site within the channel through which arachidonic acid must insert to be metabolized (Figure 1). In contrast, aspirin produces an irreversible alteration in the conformation of the active site such that arachidonic acid can no longer gain access. Aspirin produces this effect by acetylating a serine residue in COX. Thus, the recovery of prostanoid synthesis after administration of aspirin is a function of the rate of turnover of COX in each tissue. The irreversible blockade of COX by aspirin accounts for the utility of this drug in the prophylaxis of stroke and myocardial infarction. Due to their reversible binding to COX, most NSAIDs are competitive inhibitors of COX. When plasma levels of the NSAID decline below a critical level, COX activity is restored. On the other hand, COX activity is only restored following aspirin administration through the synthesis of new enzyme. Platelet aggregation is regulated by two key prostanoids. Thromboxane produced by the platelet stimulates aggregation, while prostacyclin produced by the vascular endothelium inhibits platelet aggregation. Following aspirin administration, endothelial prostacyclin synthesis is inhibited until such time as new COX is synthesized (the plasma half-life of aspirin is only ~15 min). However, platelets lack the nuclear machinery to synthesize new COX, so aspirin effectively blocks their ability to synthesize thromboxane permanently. Thromboxane synthesis only returns with the appearance of new platelets in the circulation. Thus, giving small doses of aspirin daily leads to marked suppression of thromboxane synthesis with little or no effect on endothelial prostacyclin synthesis, thereby producing a net antithrombotic effect.

In recent years, it has become clear that COX exists in at least two distinct forms. COX-1 is constitutively expressed in many tissues, including the stomach, kidney and platelet, and is believed to produce the prostaglandins that mediate important physiological functions in these tissues (Figure 2). On the

Figure 1 Cyclooxygenase metabolizes arachidonic acid to prostaglandins G and H, which are in turn converted to a number of bioactive prostanoids (PGE_2 , PGI_2 , TXA_2). Arachidonic acid inserts into a channel in COX (panel A) and can then undergo conversion to $\text{PGG}_2/\text{PGH}_2$ (panel B). Most NSAIDs bind to a site within the channel through which arachidonic acid must insert to be metabolized, thereby blocking the activity of COX (panel C). Aspirin acetylates a serine residue in COX resulting in a conformational change in the active site, such that arachidonic acid can not be converted to $\text{PGG}_2/\text{PGH}_2$ (panel D).

other hand, COX-2 is not constitutively expressed in many tissues, but can be induced in many tissues by a number of cytokines and mitogens. NSAIDs currently on the market are nonselective, inhibiting both isoforms of COX. As mentioned above, aspirin is able to produce its inhibitory effects on both COX-1 and COX-2 through acetylation of a serine residue, although the position of this residue differs slightly between the two COX isoforms. COX-2 has also

Figure 2 Arachidonic acid is metabolized by the enzyme cyclooxygenase (COX) to form prostaglandins. It has been suggested that the COX-1 isoform is responsible for producing prostaglandins important to the function of the gastrointestinal (GI) tract, kidney and platelet, while COX-2 is expressed at sites of inflammation and produces the prostaglandins that contribute to the associated pain, swelling and redness. Currently marketed NSAIDs show little selectivity for COX-1 versus COX-2, perhaps explaining their detrimental effects on the gut and kidney when used at doses required to reduce inflammation.

been shown to be the predominant form of COX expressed at sites of inflammation. This has given rise to the hypothesis that NSAIDs reduce inflammation through their inhibitory effects on COX-2, while producing their toxicity in the gastrointestinal tract and kidney through inhibitory effects on COX-1. If this is true, highly selective inhibitors of COX-2 should produce the beneficial effects of NSAIDs without the toxicity they exhibit in some tissues. This hypothesis is supported by considerable data, although there is evidence of prostaglandins derived from COX-2 performing important physiological functions in some circumstances, such as in situations in which the gastrointestinal tract is inflamed (see below).

Other mechanisms of action of NSAIDs

While there is very strong evidence supporting the hypothesis that NSAIDs produce their anti-inflammatory, analgesic, antipyretic and antithrombotic effects through inhibition of prostanoid synthesis, there is also evidence for other mechanisms of action. These other mechanisms of action may explain the differences in activity from one NSAID to another. For example, NSAIDs such as indomethacin have been shown to inhibit other enzymes, including phospholipase A₂, diacylglycerol kinase and diacylglycerol lipase. These effects are observed at concentrations achieved by therapeutic doses of these drugs, and may explain the observation that some drugs, including indomethacin, are more potent as anti-inflammatory agents than they should be based solely on their potency as inhibitors of COX.

Many NSAIDs have also been shown to inhibit the motility of neutrophils and monocytes, which could

explain their ability to reduce the number of inflammatory cells emigrating to sites of injury. Some NSAIDs have also been shown to suppress the function of helper T cells and B cells. However, at least in some cases, these effects are seen only with supra-therapeutic concentrations of the drugs.

There may also be COX-related effects of some NSAIDs that contribute to their beneficial effects, but are not due to inhibition of the activity of this enzyme. For many years, researchers have been puzzled by the observation that salicylic acid, the metabolite of aspirin, could reduce inflammation without having significant effects on COX activity. It appears that one of the mechanisms through which salicylate acid produces this effect is by inhibiting the induction of COX-2 at sites of inflammation, possibly by blocking the activity of the transcription factor NF κ B (which regulates the expression not only of messenger RNA for COX-2, but also of a number of other proinflammatory mediators).

Proinflammatory effects of NSAIDs

Ironically, while prostaglandins are typically described as mediators of inflammation, these substances exert a wide range of anti-inflammatory effects (Figure 3). For example, prostaglandins are potent inhibitors of the release of tumor necrosis factor α (TNF α) and IL-1 from macrophages, and potent inhibitors of TNF α and platelet-activating factor from mast cells. Prostaglandins also suppress the release of a number of proinflammatory mediators from platelets. On the other hand, NSAIDs, by suppressing endogenous prostaglandin synthesis, can increase the release of a number of proinflammatory mediators from various cells, and can therefore enhance an inflammatory reaction (while simultaneously reducing edema and pain). Prostaglandins have also been shown to be potent inhibitors of adhesion molecule expression on the vascular endothelium (e.g. ICAM-1) and on leukocytes (e.g. CD11/CD18), thereby reducing the ability of leukocytes to extravasate. Conversely, NSAIDs have been shown to increase adhesion molecule expression in some experimental models, and to cause a corresponding increase in leukocyte adherence to the vascular endothelium. Actions such as these might explain the observation that NSAIDs can actually lead to increased tissue injury in some forms of inflammation, as well as some of the adverse reactions to NSAIDs in settings of inflammation (e.g. inhibition of the healing of peptic ulcers). Removal of the immunomodulatory effects of endogenous prostaglandins through NSAID administration may

Figure 3 Prostaglandins exert both pro- and anti-inflammatory effects. Prostaglandins, through vasodilation, increase edema formation. However, prostaglandins can reduce inflammatory reactions through inhibition of adhesion molecule expression on the vascular endothelium, and inhibition of inflammatory mediator release from macrophages, mast cells and platelets. Prostaglandins can also reduce tissue injury through inhibition of oxygen-derived free radical production by leukocytes and monocytes.

also contribute to the hypersensitivity reactions to these drugs (see below).

Adverse effects of NSAIDs

Like the beneficial effects of NSAIDs, the adverse effects of these drugs can be largely attributed to their effects on prostaglandin synthesis. The most common detrimental effects of NSAIDs are ulceration in the gastrointestinal tract, renal damage, delayed labor and hypersensitivity reactions (often manifest as asthma). NSAIDs can cause gastric and duodenal ulceration and can exacerbate or delay the healing of pre-existing ulcers. Inhibition of prostaglandin synthesis in the upper gastrointestinal tract is central to the pathogenesis of this ulceration. On the other hand, small intestinal damage caused by NSAIDs may be more a consequence of their topical irritant properties and enterohepatic recirculation than to inhibition of prostaglandin synthesis. Renal injury by NSAIDs, which includes papillary necrosis and chronic interstitial nephritis, is also believed to be, at least in part, attributed to inhibition of prostaglandin synthesis. Prostaglandins play an important role in autoregulation of renal blood flow, with a particularly important role being played in individuals with renal and/or hepatic insufficiency. In the case of delayed labor, once again it is the suppression of prostaglandin synthesis that causes alterations in uterine contraction; however, there is evidence that the prostaglandins in this case are derived largely from COX-2, which is induced in labor. Similarly, in settings of gastrointestinal inflammation, such as in inflammatory bowel disease and peptic ulcer disease, the exacerbation of inflammation and delayed

healing of ulcers may be due to inhibitory effects of NSAIDs on COX-2. Because of this, the notion that selective COX-2 inhibitors will be devoid of toxicity, particularly in the gastrointestinal tract, may have to be reconsidered in cases where individuals have a pre-existing inflammatory disease in those tissues in which COX-2-derived prostaglandins appear to play an important immunomodulatory and anti-inflammatory role.

Hypersensitivity reactions to NSAIDs are not common in children, but may occur in up to a quarter of middle-age patients. The reaction, which can range in severity from rhinitis and bronchial asthma to hypotensive shock, can be life-threatening and can occur following ingestion of small doses of these drugs. While often regarded as occurring only with aspirin, hypersensitivity reactions can occur with any NSAID. The mechanism responsible for this reaction has not been firmly established, but does not appear to be immunological in nature. However, as it can occur with NSAIDs with diverse chemical structures, the reaction may be related to suppression of COX. There is evidence that administration of NSAIDs to susceptible individuals results in a profound increase in the production of peptido-leukotrienes, which are potent proinflammatory and bronchoconstrictive agents. These substances are also derived from arachidonic acid, so the increase in leukotriene synthesis may be a consequence of 'shunting' of substrate to that pathway when COX is inhibited, or due to the removal of the inhibitory effects prostaglandins can exert on leukotriene synthesis.

ANTI-LYMPHOCYTE SERUM

Göran Sandberg, Lymphocyte Unit, Department of Neuroscience, Karolinska Institute, Stockholm, Sweden

Anti-lymphocyte serum (ALS) is a serum which contains antibodies against lymphocytes, and is usually prepared in horse, goat or rabbit by immunization with human lymphoid cells. ALS may be obtained by immunization with, for example, lymph node cells, T cell lines, B cell lymphoblasts, thoracic duct lymphocytes or thymocytes. In the latter case the produced serum is referred to as antithymocyte serum (ATS). Most often, the immunoglobulin (Ig) fractions of ALS or ATS were isolated and used as anti-lymphocyte globulin (ALG) or antithymocyte globulin (ATG). Removal of cross-reacting antibodies (such as to erythrocytes or platelets) reduces the side-effects. Some frequently used preparations are ATGAM (equine ATG), Lymfoser, Minnesota anti-lymphoblast globulin (MALG), and different RATG (rabbit ATG) preparations, such as ATG Fresenius, Nashville antithymocyte serum (nATS), and thymoglobulin. In this text, all these different preparations are referred to as ALS. With modern techniques, highly specific monoclonal antibodies (mAbs) against different cell surface molecules have been prepared, and are used in a similar fashion as ALS. Both with polyclonal ALS and mAbs, the effects may be counteracted by sensitization against the xeno-geneic proteins.

ALS as an immunosuppressive agent

ALS is used, often in combination with other immunosuppressive agents, to avoid allograft rejection. In a quadruple therapy protocol it is used with azathioprine, steroids and cyclosporine. ALS is used both as a preventive immunosuppressant, for initial

treatment of rejections, and to treat steroid-resistant rejection. The mechanism of action is not fully clarified, but depletion of circulating lymphocytes does occur. This may result from either cytotoxic mechanisms or opsonization. The widest experience with ALS is from kidney transplantation, but ALS has also been used in connection with transplantation of small bowel, heart, bone marrow, liver, pancreas (or islet cells), cornea and skin.

ALS in bone marrow disease and bone marrow transplantation

ALS is widely used in the treatment of bone marrow disorders, particularly severe aplastic anemia. When bone marrow transplantation is not possible, ATG represents the second-best therapeutic alternative in aplastic anemia. It has also been used together with bone marrow transplantation and with good results.

The graft-versus-host reaction is a persistent problem in bone marrow transplantation. The removal of mature T cells and T cell precursors with different lymphocyte-specific antibodies has been a way of preventing it. There are, however, studies that claim that the removal of T cells from bone marrow before transplantation does not improve survival rates, and in fact can cause a higher frequency of graft failure.

An antigen on T lymphocytes which is a very good target for cell lysis is the CDw52 antigen. mAbs to this antigen, prepared in the rat (CAMPATH-1), have been used successfully to deplete donor bone marrow of T lymphocytes. The variants CAMPATH-1G (IgG2b) and CAMPATH-1M (IgM) exist, as well as the humanized CAMPATH-1H (human IgG1).

Therapeutic use of ALS in other diseases

Other cases in which ALS has been reported of value include autoimmune disease such as rheumatoid arthritis and multiple sclerosis, autoimmune thrombocytopenic purpura, Omenn's syndrome, Wegener's granulomatosis, pure red cell aplasia and familial hemophagocytic lymphohistiocytosis. The use of ALS in these conditions is not widespread, however, possibly because of problems related to repeated treatment, such as reduced effect, or anaphylactic reactions. In mice, ALS (or anti-CD4 mAbs) prevents the development of spontaneous systemic lupus (NZB strain) and diabetes (NOD strain). Experimentally induced diabetes (BALB/c strain), arthritis and myasthenia gravis are also prevented this way. In addition, ALS or more specific antibodies may prove to be useful in leukemia. A monovalent, CD3-specific mAb has been shown to deplete CD3⁺ tumor cells effectively in a patient with T cell leukemia. CAMPATH-1 is very effective in the treatment of lymphoid malignancy and lymphoproliferative diseases. This mAb has also been tried in the treatment of rheumatoid arthritis and multiple sclerosis.

Monoclonal anti-lymphocyte antibodies

Although the polyspecific ALS (shown to contain antibodies to a great number of T lymphocyte surface antigens) is still very useful, with the advent of monoclonal antibodies to various surface molecules on lymphocytes, more specific tools are available. Antibodies specific for epitopes on molecules such as CD2, CD3/TCR components, CD4, CD6, CD8, IL-2R (CD25), LFA-1, and HLA class II have been tried. OKT3 (anti-CD3), which is by far the most commonly used mAb to lymphocytes, has been used for immunosuppression in clinical practice for about 15 years. It has a half-life after injection of 18 h. As with ALS, such mAbs will be used for depletion of lymphocyte populations, but may also be used to modulate the function of lymphocytes by way of interacting with the respective surface molecules. Many studies have compared the therapeutic use of OKT3 and ALS, and in many cases they were found to be equivalent. OKT3 has been effective in cases where graft rejection was both steroid and ALS resistant. Many factors influence the effectiveness of lymphocyte-specific mAbs, such as the properties of preparation itself, the pharmacokinetics, the rate of production of the target molecules, the presence of blocking antibodies, etc. Advantages with mAbs are that they are uniform in immunoglobulin subclass and have a better defined specificity and more repro-

ducible effects. A problem is the production of anti-antibodies which counteract the effect of the administered mAb (Figure 1). It is a smaller problem when using polyclonal ALS, and is to some extent prevented by the use of concomitant immunosuppression. The problem with anti-antibodies may be circumvented by changing to a mAb against a different epitope or by using mAbs with a human type of molecular structure. In an experimental system, pretreatment with ALS was found to suppress formation of neutralizing anti-antibody to a mAb administered later. Only mAbs against CD4 seem to avoid stimulating the production of anti-antibodies by the recipient. This may reflect the unique ability of CD4-specific mAbs to induce tolerance. A humanized CD4-specific mAb has been used in clinical trials on patients with autoimmune disease. The effect of mAbs may be modified by removing the Fc fragment, which is of importance for the elimination of the target cells by phagocytes. Thus, CD3-specific mAbs which lack the Fc part cause immune activation rather than immunosuppression. Antibodies may be raised against the antigen-binding epitope of the T cell receptor. This will probably become of value in the treatment of autoimmune disease. In the comparison between ordinary, polyclonal ALS and mAbs, contradictory opinions have been published regarding the effectiveness and severity of side-effects.

Side-effects

ALS is administered via a central nervous catheter to avoid irritation following intramuscular or ordinary intravenous injection. Many side-effects seen after administration of polyclonal or monoclonal antibodies against lymphocytes are probably due to antibodies cross-reacting with other tissues. A common problem is serum sickness (fever, malaise, dyspnea, hypotension, edema, cutaneous eruptions, lymphadenopathy, arthralgia and headache). Histologically there may be signs of vasculitis. Many of these symptoms seem to be associated with occurrence of immune complexes. Monoclonal antibodies also have side-effects, even in their humanized forms. The first few injections of anti-CD3 often cause fever, gastrointestinal and respiratory disturbances, headache and anorexia, symptoms sometimes referred to as 'the first-dose syndrome'. The side-effects caused by both ALS and anti-CD3 are thought to be mediated by release of tumor necrosis factor (TNF), interferon γ (IFN γ) and possibly interleukin 2 (IL-2). Transient renal dysfunction attributed to cytokine-induced renal capillary leakage, has also been reported. Other T cell-specific mAbs do not cause

Figure 1 Measurement of a human antimouse antibody response to therapeutic Mabs. An antimouse antibody is first bound to a surface (A). The therapeutic mouse Mab is then added, together with the human serum to be examined (1; B, C). Lastly, an antihuman Ig antibody is added (2; D). The binding of this last antibody is dependent on the presence of antimouse antibodies in the patient's serum.

cytokine release and do not result in so many side-effects. More rarely, symptoms from the central nervous system may occur. There is a risk of lymphoproliferative conditions with both ALS and OKT3, at least after extended use. It has been suggested that side-effects of ALS may be minimal with a remaining therapeutic effect if the administration of ALS is adjusted according to the daily level of T lymphocytes in the blood. Of course, the immunosuppressive effects of both polyclonal and monoclonal lymphocyte-specific antibodies are associated with a risk of opportunistic infections.

Mechanism of action and methods of monitoring ALS before and during clinical use

There is a great need for reliable methods of evaluating the effectiveness of various ALS preparations before they are used on patients. However, as long as the mechanism of action is not clearly established, it is hard to identify the method of choice. The immunosuppressive effect of ALS may be mediated by depletion of lymphocytes from blood and lymph-

oid tissue. This is accomplished by the opsonizing effect of antibodies, stimulating phagocytosis of the lymphocytes. Other possibilities are blocking or modulation of receptors on lymphocytes. While OKT3 causes depletion of blood T lymphocytes, these cells, although antigenically modulated, may persist in peripheral lymphoid organs. It has also been reported that ALS may induce expansion of unusual subpopulations of lymphocytes. Also, donor-specific antigen-dependent suppressor cells may maintain the allograft tolerance induced by ALS. The effect of ALS on severe aplastic anemia has been ascribed to the release of hematopoietic growth factors (such as granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-3), stimulation of hematopoietic cells via CD45RO, blocking of Fc receptors for IgG on T cells, or interference with activated T lymphocytes which inhibit hematopoiesis.

Among the *in vitro* methods used for tests of ALS activity are the study of specificity for different epitopes, the monitoring of cytotoxic or mitogenic effects, inhibition of the binding of sheep erythrocytes to T cells via CD2 (rosette inhibition), opsonizing effect on lymphocytes, quantitation of antibodies

bound to lymphocytes or of macrophage-cytophilic antibody, or methods based on complement binding. The potential of an ATG preparation can be estimated by titration of the dose which gives a 50% inhibition of binding of a panel of mAbs to lymphocyte markers. Owing to relatively poor correlation between *in vitro* tests and the immunosuppressive effect of ALS, *in vivo* testing of antihuman ALS preparations has also been performed. For instance, effects on graft-versus-host reactions in rats, and the rejection of skin allografts in monkeys, were shown to correlate well with immunosuppressive effects on patients. It is possible to examine the effectiveness of treatment by measuring target cell concentrations in the blood, or the density of target antigens on such cells. Also, the immunological response to the administered ALS or mAbs may be quantitated by various methods such as ELISA. Such measurements are important in the planning of a repeated treatment with ALS.

Experimental use of ALS

In addition to the wide clinical use of ALS, it can be used for both the identification of lymphocyte subsets and for isolation of such populations. This can be achieved either by negative selection (complement-mediated lysis) or positive selection (e.g. by means of adherence to antibody-coated surfaces). However, mAbs are mainly used for these purposes today. ATS-treated mice can be used in an assay for tumorigenicity and metastatic capacity of cancer cells.

Natural and disease-associated lymphocyte-specific antibodies

In the blood of normal individuals one finds lymphocyte-specific antibodies which, under certain conditions, may be cytotoxic to all, or to subpopulations of, lymphocytes. These antibodies are part of the natural antibodies found in nonimmunized individuals. The significance of these antibodies is not clear, but their presence may induce acute rejection of a transplanted tissue. Autologous antibodies against lymphocytes seem to be induced by virus infections. They also occur in increased frequency in autoimmune disease (systemic lupus erythematosus, rheumatoid arthritis, ankylosing spondylitis), cancer, and in patients exposed to alloantigen, such as multiple transplanted uremic patients, multiparous dialysis patients, hemophiliacs and male homosexuals. A large percentage of patients with Behçet's syndrome have lymphocytotoxic antibodies, as do some of their healthy children. The presence of lymphocyte-

specific antibodies in human immunodeficiency virus (HIV) infection is associated with increased risk for developing acquired immune deficiency syndrome (AIDS). Such antibodies may have been produced as a result of an immune response against lymphocyte-bound HIV determinants (such as gp41) and may directly cause the lymphopenia in AIDS patients. Autoantibodies to CD4, found in some HIV patients, do not however appear to have a prognostic significance. Autoantibodies to the GM3 ganglioside on AIDS patients' lymphocytes have been detected which do not bind to normal GM3.

Sera with natural lymphocytotoxic antibodies to heterologous cells have not been used therapeutically but may have an experimental value. For instance, natural thymocytotoxic antibodies from rabbits have been used in experiments on guinea pigs to deplete thymus cells of immature populations.

ANTI-NUCLEAR ANTIBODIES

RJT Smeenk, Central Laboratory of the Netherlands Red Cross, Amsterdam, The Netherlands

TEW Feltkamp, Research Center for Rheumatic Diseases, Amsterdam, The Netherlands

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Antibodies against antigens of cell nuclei probably occur in the blood of all human beings. Since such antibodies generally react with all kinds of nuclei, whatever their origin, they are also directed against antigens in the nuclei of the host, and are therefore considered to be 'autoantibodies'. If the anti-nuclear antibodies (ANAs) occur in titers elevated significantly above the normal serum level, the employed test is considered 'positive'. Such high titered autoantibodies are especially associated with the autoimmune disease systemic lupus erythematosus (SLE), although they also occur in high frequencies in patients with rheumatoid arthritis (RA), Sjögrens syndrome, scleroderma, polymyositis, mixed connective tissue disease (MCTD), myasthenia gravis and chronic active hepatitis.

ANA were first demonstrated in 1957 by Holborow and by Friou, using the indirect immunofluorescence technique (IFT) as developed by Coons. This method is still the method of choice as a screening technique, before more specific methods are used. The distinct ANAs and the assays used to demonstrate their presence are listed in Table 1.

Nuclear antigens

Nucleus

Many distinct structures in the cell nucleus serve as antigen for different populations of ANAs. Most ANAs are directed against nucleic acids or against proteins associated with nucleic acids. Only nucleoli and centromeres of chromosomes can readily be distinguished by the IFT as separate antigenic entities, all other antigens for autoantibodies have to be determined with more specific methods. The centromere antigen complex contains at least three antigenic proteins: CENP-A (18 kDa), CENP-B (80 kDa) and CENP-C (140 kDa).

Nucleosome

The nucleosome is the basic structure of chromatin and has an important function in the compaction of DNA in the nucleus of the cell. It consists of dimers of the four core histones, H2A, H2B, H3 and H4, together forming a histone-octamer around which 146 base pairs of DNA are wrapped twice (Figure 1). Two nucleosome subunits are connected via a

Figure 1 Schematic drawing of chromatin and its subunit, the nucleosome.

stretch of linker DNA to which histone H1 is bound. The four core histones are single-chain polypeptides with molecular weights ranging from 11 to 15 kDa. Clustered at the N-terminal regions of the core histones are basic residues, which, therefore, are located at the outside of the nucleosome. These positive charges on the cylindrical surface of the histone octamer form a left-handed spiral, situated along the DNA and are partly involved in the binding of DNA.

Small nuclear RNP (snRNP)

Eukaryotic cells contain a number of distinct small RNA molecules, which can be broadly divided into two classes: the capped small nuclear RNAs (snRNAs or U-RNAs) and the uncapped small cytoplasmic RNAs (scRNAs). Mammalian cells contain at least 14 different U-RNAs, organized into ribonucleoprotein particles (U-snRNPs; **Figure 2**). The

Figure 2 Schematic drawing of a U-snRNP particle. To the U1-RNA molecule the proteins 70 kDa, A, C and those of the Sm complex are bound; the Sm complex encompasses the proteins BB', D1, D2, D3, E, F and G.

U1–U6 snRNPs, with the exception of U3 snRNP, have an important role in messenger RNA processing.

More than 25 different polypeptides have been identified as constituents of the major snRNPs U1, U2, U5 and U4/U6. Of these proteins, nine are present in each of the individual snRNPs, and are designated as Sm or core proteins (**Table 2**). These include the BB' doublet, the D1/D2/D3 triplet and the E, F and G polypeptides. In addition to the core proteins, most of the snRNPs contain a number of unique polypeptides, designated 70 kDa protein, A and C (found in U1 snRNP only), A' and B' (found only in U2 snRNP).

RA-33

So-called heterogeneous nuclear ribonucleoproteins (hnRNPs) are complexes of RNA-polymerase II transcripts and a number of proteins. In these complexes, the processing of hnRNA into mature RNA takes place. Amongst the proteins in the hnRNP-complexes are the hnRNP-A1 and -A2. The latter has been shown to be identical to the RA-specific antigen RA-33.

Ku

The Ku antigen is localized in a particle composed of two noncovalently linked proteins of 70 and 80 kDa that bind DNA. The antigen is identical to nuclear factor IV (NF IV). Both proteins have been cloned and epitope mapping studies indicate that the major epitopes recognized by anti-Ku antibodies are conformational.

PCNA

Proliferating cell nuclear antigen (PCNA), also named cyclin, is a protein of 29 kDa that is primarily present in dividing cells. It has been identified as an auxiliary protein of DNA polymerase δ , a particle involved in DNA replication.

Nuclear enzymes

Several nuclear enzymes serve as antigen for auto-antibodies. Topoisomerase I is the most important of these. It is an enzyme of 100 kDa which is involved in the relaxation of supercoiled DNA, by nicking and releasing one strand of the DNA duplex.

Cytoplasmic antigens

ANAs are, by definition, directed to antigens in the cell nucleus. Since many patients with generalized autoimmune diseases not only have antibodies to nuclear antigens but also to cytoplasmic antigens,

Table 2 Presence of proteins in U-snRNP particles

	70 kDa	A	A'	B	B'	B''	C	D1-3	E	F	G
U1-RNP	✓	✓		✓	✓		✓	✓	✓	✓	✓
U2-RNP			✓			✓		✓	✓	✓	✓
U5-RNP				✓	✓			✓	✓	✓	✓
U4/U6-RNP				✓	✓			✓	✓	✓	✓

these are generally also loosely included under the term 'ANA'.

Small cytoplasmic RNP (scRNP)

One of these cytoplasmic antigens is called La/SS-B. It functions as a termination factor for RNA polymerase III. Therefore, La/SS-B scRNPs are composed of an RNA polymerase III transcript to which the La/SS-B protein is bound (Figure 3). The RNA transcripts include 7S RNA, 5S RNA, tRNA, U6-RNA, the Y-RNAs as well as a number of viral RNAs.

Ro/SS-A scRNPs are composed of several proteins complexed with a subset of the La/SS-B associated RNAs, the so-called Y-RNAs (Figure 3). In human cells four different Y-RNAs have been identified, together with two different Ro/SS-A proteins, designated Ro52 and Ro60. The Ro60 protein is unusual in containing both an RNP consensus motif for binding RNA and a zinc finger motif for binding to DNA. The Ro52 protein contains multiple zinc fingers and a leucine zipper sequence, but no RNP consensus motif. Most probably, this protein is complexed to Y-RNPs via binding to the Ro60 protein. The 50 kDa La/SS-B protein contains, as expected, an RNP consensus motif.

About 30% of both Ro/SS-A and La/SS-B is localized in the nucleus of the cell, which explains the nuclear immunofluorescence of anti-Ro/SS-A and anti-La/SS-B. Contrarily, Y-RNAs are predominantly

cytoplasmic. Presumably, Ro/SS-A and La/SS-B bind to newly synthesized Y-RNA in the nucleus, after which the mature complex, termed scRNP is transported to the cytoplasm.

No function has as yet been associated with the Ro/SS-A proteins.

rRNP

Ribosomal P-proteins are phosphorylated proteins that are present, often in multiple copies, on the ribosome. P1 (19 kDa) and P2 (17 kDa) interact with the eukaryotic elongation factors EF1 and EF2 and play a role in aminoacyl-tRNA binding and polypeptide synthesis. These proteins share a 22 amino acid sequence at the C-terminal that contains an epitope recognized by so-called anti-rRNP or anti-P antibodies.

Cytoplasmic enzymes

Aminoacyl-tRNA synthetases are a group of cytoplasmic enzymes that catalyze the binding of tRNA to their respective amino acids. A number of them have been identified as antigens for a special class of ANA.

Detection, identification and clinical significance of ANAs

ANAs with IFT

The IFT is generally used as a screening assay for the presence of ANAs. The method is highly sensitive and detects almost all ANA specificities. Most laboratories now use cultured cells as substrate instead of tissue sections. Sera from patients with generalized autoimmune diseases mostly have several distinct ANAs at the same time. Since the titers of these antibodies differ, titration of the serum can reveal the strongest ANAs giving a certain pattern of nuclear fluorescence. Homogeneous patterns are frequently observed in patients with SLE or rheumatoid arthritis (RA), speckled or granular patterns in sera from patients with Sjögren's syndrome or scleroderma. Nucleolar fluorescence is often seen in patients with progressive systemic sclerosis (PSS). These associations, however, are of limited value to the clinician.

**Figure 3** Schematic drawing of an scRNP particle.

Only the discrete speckled pattern of nuclear fluorescence is informative, since this points to the presence of antibodies to centromeres. This should be confirmed by performance of the IFT on mitotic cells or chromosome spreads. Also the presence of other types of nuclear fluorescence is mostly the start of studies to specify the kind of the ANA.

Nearly all patients with SLE have ANAs, mostly in high titers. In RA, Sjögren's syndrome, PSS, MCTD, myasthenia gravis and chronic active hepatitis the frequency of the ANAs and the titers of these antibodies are considerably lower (Table 3).

A negative result in the IFT does not necessarily mean that ANAs are not present. It is known that low titered reactivities to Ro/SS-A, rRNP and Jo-1 are relatively difficult to detect in this assay.

Most laboratories have tested sufficient sera from healthy individuals to be aware of the statistical limits between normal and pathological ANA titers. Nevertheless, it should be noted that not only generalized autoimmune diseases show a preponderance for women and adults, but that also healthy elderly women have a far greater tendency to show these antibodies than young boys. A positive ANA in a boy, therefore, draws more attention than the same ANA in a woman over 60 years of age.

LE cell test

In 1948 Hargraves described for the first time the

occurrence of LE cells. The demonstration of these cells was a great help to define the complicated clinical picture of SLE (Table 3). Later on, the 'LE cell factors' were identified as autoantibodies and the 'LE cells' as granulocytes which had phagocytosed complexes of these autoantibodies and nuclei of other cells. Nucleosomes are able to inhibit the formation of 'LE cells', in contrast to free dsDNA or histones. Thus, it appears that the LE cell phenomenon is related to the presence of antinucleosome autoantibodies. After 45 years the test is still in use but with the introduction of more specific methods, it has become somewhat redundant.

Anti-DNA

Antibodies to DNA can be found in the circulation of the majority of patients with SLE. They are quite specific for this disease, which makes their detection an important diagnostic aid to the clinician (Table 3). Fluctuations in the level of anti-dsDNA in an individual patient generally parallel the clinical status of that patient. Under defined conditions, increases in the level of anti-DNA predict an upcoming flare of the disease. Indeed, it has recently been shown that instalment of (prednisone) treatment on the basis of increasing levels of anti-DNA may prevent the exacerbation from becoming overt. Furthermore, the presence of anti-dsDNA may precede the diagnosis of SLE by more than a year.

Table 3 Frequencies of ANA in various autoimmune diseases (percentages in round figures)

nk, not known. SLE, Systemic lupus erythematosus; RA, rheumatoid arthritis; SS, Sjögren's syndrome; MCTD, mixed connective tissue disease; PSS, progressive systemic sclerosis; CREST, CREST syndrome (variant of scleroderma); PM-DM, Polymyositis-dermatomyositis.

A multitude of assays have been developed to detect the presence of antibodies to DNA. Currently, the most commonly used assays are the IFT on *Crithidia luciliae*, radioimmunoassays (RIAs) such as Farr assay and PEG assay, and enzyme-linked immunosorbent assays (ELISAs). These methods can either be obtained in kit form or be employed as in-house assays. The hemoflagellates *Crithidia luciliae* which are used in the IFT contain a giant mitochondrion, the kinetoplast, which consists of only double-stranded DNA. To facilitate discrimination between nuclei and kinetoplasts, the slides are counterstained by propidium iodide, which intercalates in the dsDNA helices. Fluorescence of kinetoplasts is taken as an indication of the presence of anti-DNA. After 20 years, this method still is one of the most frequently employed techniques for the detection of anti-DNA. The method is specific and quite sensitive. In RIAs the choice of antigen again is of great importance. The DNA employed has to be bigger than 10⁵ but smaller than 10⁷ kDa. Furthermore, the DNA must be double stranded and, to allow quantitation of antibody reactivity, monodisperse in size. This indicates that circular double-stranded bacteriophage DNA (such as from PM2) or plasmids (such as pUC9) are to be preferred.

In ELISA systems, DNA has to be coated to plastic. ssDNA can easily be coated directly, but dsDNA is mostly coated via intermediates such as poly-L-lysine, protamine or methylated BSA. Such precoats introduce problems related to the binding of immune complexes and/or immunoglobulins not directed against DNA to the plates (via the intermediate molecule). An alternative is to make use of biotinylated DNA and coat this via streptavidin to the plates.

Different assay systems are not always comparable, for the following reasons:

1. The source of antigen differs: DNA may be from

eukaryotic or prokaryotic origin, be double stranded or single stranded, be polydisperse in size or homogenous, etc.

2. Presentation of the antigen to the antibody differs: in RIAs it is generally in solution, in ELISAs it is coated to plastic; in the *Crithidia* test DNA is mostly presented intact in cells.
3. Reaction conditions are different: e.g. due to the employed ammonium sulfate precipitation step used in the Farr assay, anti-dsDNA of low avidity is missed with this method; in second antibody techniques such as IFT and ELISA the choice of conjugated antibody is of importance; often, only IgG anti-DNA is measured with these techniques.

General comparison of four different assays using sera of patients with defined SLE leads to high levels of correlations between the various assays (Table 4). However, upon routine screening of sera from patients suspected as having generalized autoimmune diseases, large discrepancies between the different assays are also seen: out of 16 possible reactivity combinations, 11 actually occurred. Sensitivity differences can only partly explain the discrepancies observed between the assays. An important cause is to be found in the avidity of the antibodies (Figure 4). Furthermore, histones or nucleosomes complexed to antinucleosome antibodies may also cause a positive reaction in the Farr assay. It is advisable to quantitate anti-DNA levels and express these in International Units, to allow comparison between different studies. A World Health Organization (WHO) standard serum to serve this purpose is available from the Central Laboratory of the Blood Transfusion Service (CLB) in Amsterdam. The CLB is the custodian of WHO standards for rheumatology.

Of the methods described, the ELISA is the most

Table 4 Comparison of the disease specificity of four anti-dsDNA assays

Disease	Number	Percentage of sera positive in			
		Farr assay	Crithidia	PEG assay	ELISA
Active SLE	96	98	96	96	100
Rheumatoid arthritis	62	1	0	5	3
Sjögren's syndrome	14	0	0	7	20
Scleroderma	12	0	0	0	30
Autoimmune hepatitis	61	0	0	20	15
Myasthenia gravis	25	0	0	32	20
Autoimmune thyroiditis	66	0	0	7	13

Autoimmune hemolytic anemia	40	0	0	10	8
Normal donors	192	0	0	0	0

Figure 4 Relation between anti-DNA avidity and assay behavior.

sensitive, whereas the Farr assay is the most specific for SLE. Using the latter method, only antibodies of a relative high avidity for DNA are detected. Mild forms of SLE, where patients only have anti-dsDNA of a low avidity in their circulation, may easily be missed by this technique. On the other hand, if screening for the presence of anti-DNA takes place using an assay that is not selective for anti-DNA of high avidity, then a positive assay result does not always indicate that the patient has SLE: anti-DNA of lower avidity occurs in diseases other than SLE. An evaluation of the diagnostic value of low avidity anti-dsDNA has shown that half of the patients in whom anti-dsDNA is PEG positive but Farr negative have SLE. When high-avidity anti-dsDNA is present as well, nearly 90% of the patients were found to have SLE. Therefore, screening using a 'broad-spectrum' method should be followed by an assay selective for high-avidity anti-dsDNA.

Because the Farr and PEG assays may readily be compared, as they only differ with respect to the way DNA/anti-dsDNA complexes are precipitated, a relative avidity index can be acquired by calculating the ratio between results (in IU ml⁻¹) of both assays. An optimal discrimination between low- and high-avidity DNA was obtained using a cut-off Farr:PEG ratio of 5. Using this approach anti-dsDNA of SLE patients with nephritis was found to have significantly higher avidity than that from patients with CNS involvement.

Antibodies to DNA have always been claimed to play an important role in the pathogenesis of SLE. Traditionally, SLE is considered to be an immune complex disease. In this concept, anti-DNA binds DNA and the resulting immune complexes are deposited in the tissues. This binding of DNA by antibodies may occur in the circulation, but it may

also happen *in situ*. At the site of deposition, subsequent complement activation then leads to inflammation and the characteristic disease features of SLE. In the past few years this concept of the pathophysiology of SLE has been challenged, and a modified hypothesis concerning the pathogenesis of SLE has been proposed. This new concept is based on studies that have shown that anti-DNA may interact with tissue structures such as heparan sulfate (HS), the major glycosaminoglycan side-chain of the glomerular basement membrane (GBM). Although it was originally thought that the binding of anti-DNA to HS was based on cross-reactivity, more recently it has been shown that this binding is in fact mediated by nucleosomes. Increased levels of nucleosomes have been demonstrated in the plasma of SLE patients, perhaps due to increased or defective apoptosis leading to their release into the circulation. Renal perfusion studies in the rat have shown that anti-DNA can only bind to the GBM after prior perfusion with histones followed by DNA, or with nucleosomes. Thus, complexes composed of antibodies and nucleosomal material interact via their histone part with heparan sulfate in the GBM. In contrast to anti-nucleosome and anti-DNA antibodies, antihistone monoclonal antibodies do not localize in the GBM after complexation with nucleosomes. Therefore, the specificity of the antibody bound to the nucleosome appears to be a critical determinant for the nephritogenic potential of the complex.

Anti-nucleosome

Anti-nucleosome antibodies are defined as antibodies which are directed exclusively (or predominantly) against nucleosomes or subnucleosomal structures, consisting of DNA plus core histones. These antibodies were in fact the first autoantibodies described in association with SLE, being the LE factors that were responsible for the so-called 'LE cell phenomenon'.

For the specific detection of antibodies to nucleosomes, ELISAs have been developed in which purified nucleosomes are used as antigen. Several purification protocols have been described, all using micrococcal nuclease digestion which causes internucleosomal cleavage. All eukaryotic cells can be used as starting material, but most frequently calf thymus or rat liver is used. After preparation, the purity should be checked, both for the histones by PAGE analysis and for DNA by extraction and analysis on agarose gels. For screening purposes, H2A-H2B/DNA can be used as a substitute for nucleosomes. To this end, commercially obtained H2A and H2B can be mixed in equal amounts; the

dimer is then coated to ELISA plates, subsequently followed by addition of dsDNA.

A problem in the measurement of antibodies to nucleosomes is, of course, that both anti-dsDNA and antihistone will also react with nucleosomes. So far, this can only be solved by prior absorption of anti-DNA and anti-histone from the serum or plasma sample. In this way, the presence of nucleosome-specific antibodies has unequivocally been demonstrated in SLE patients. From analysis of the epitope specificity of a number of lupus-derived nucleosome-specific monoclonal autoantibodies, it is clear that these antibodies recognize a multitude of conformational epitopes formed by the interaction between DNA and core histones.

Anti-histone

Anti-histone antibodies occur in a number of autoimmune diseases, including SLE, drug-induced lupus, juvenile rheumatoid arthritis and RA (Table 3). The frequency of autoantibodies to individual histones vary according to the type of autoimmune disease. In general, antibodies to H1 are the most frequent in SLE, followed by anti-H2B, anti-H2A, anti-H3 and anti-H4, respectively. Antibodies to histones are generally measured by means of specific ELISAs, using purified histones as antigens. Care has to be taken regarding the purity of commercial histone preparations. Antihistone reactivity is also readily detectable in immunoblotting assays, using nuclear extracts as antigen.

Anti-centromere

These antibodies can be demonstrated with the IFT on cultured cells. A more sophisticated assay makes use of chromosome spreads on slides, to allow the specific localization of the centromeres.

Antibodies to the centromere antigens CENP-A and CENP-B are the most common and can be found in about 95% of the patients with the CREST syndrome (Table 3). They occur less frequently in patients with diffuse scleroderma, and are, therefore, important diagnostic markers for scleroderma with limited skin involvement. They also appear to have prognostic significance. Anti-centromere reactivity is readily measured by IFT and immunoblotting; CENP-B has been cloned and can be used in ELISA.

Anti-snRNP (Sm, U1-RNP, U2-RNP)

Sm-specific antibodies are directed to the D proteins (either all three or to a subset of them) and to the BB' doublet of the U-snRNPs (Figure 2). Since these proteins are common to all major snRNPs except U3, Sm-specific antibodies precipitate U1, U2, U4,

U5 and U6 snRNPs. Whereas these antibodies to Sm are exclusively found in patients with SLE, and are, therefore, disease specific, antibodies to U1-RNP are considered to be a marker antibody for MCTD (Table 3).

Anti-U1-RNP sera precipitate U1-snRNPs; they predominantly recognize U1-70 kDa and U1-A, and with lower frequency also U1-C. In about 50% of the cases U1-RNP sera also react with BB'. Antibodies to U2-RNP react predominantly with the U2-snRNP-specific B'' protein, and in some cases also with the U2-A' protein.

Apart from detection by counterimmunoelectrophoresis (CIE) and immunoblotting, specific ELISAs have also been developed for the measurement of anti-Sm and anti-U1-RNP. Most of the relevant proteins are available in recombinant form, for use in ELISA systems. For some unexplained reason, the recombinant D protein(s) is (are) not immunoreactive in ELISA and cannot be used.

Presently available data on the incidence of anti-Sm and anti-U1-RNP in autoimmune diseases has been compiled using 'older' assays, such as CIE. Data obtained using immunoblotting and ELISA are not readily available.

Anti-RA-33

Antibodies to RA-33 were originally described to be quite specific to RA. More recently they have also been found in other autoimmune diseases (Table 3). They can be detected by immunoblotting, where they generally give rise to a trimer of around 33 kDa.

Anti-Ku

Ku-specific antibodies were originally described in Japanese patients with scleroderma-polymyositis overlap syndromes. Later, it was observed that these antibodies also occur in patients with SLE, scleroderma and MCTD (Table 3). They can be detected by immunofluorescence, CIE and immunoblotting.

Anti-PCNA

Antibodies to PCNA are found in the sera of about 3% of SLE patients, and can be detected by IFT in dividing cells (Table 3). The antibody is also readily detectable by CIE and immunoblotting, where it shows a band at 35 kDa. Epitope mapping studies have shown that the antibodies primarily bind conformational epitopes in this antigen.

Anti-topoisomerase I (Sci70)

Antibodies to topoisomerase I, mostly termed anti-Sci70, are found frequently in sera of patients with diffuse cutaneous systemic sclerosis and are quite

specific to this disease (Table 3). Therefore, anti-Scl70 is an important marker antibody for systemic sclerosis. Anti-Scl70 can be detected by CIE, immunoblotting or a specific ELISA. The presence of this antibody in patients with Raynaud's phenomenon that eventually develop scleroderma suggests that anti-Scl70 may have prognostic significance.

Anti-scrNP (Ro/SS-A, La/SS-B)

Antibodies to La/SS-B are predominantly found in patients with Sjögren's syndrome, but also in SLE and in RA (Table 3). Differences in reported percentages are to be explained on the basis of patient selection and use of different methods of the detection of anti-La/SS-B. Analysis of immunoglobulin heavy and light chain usage has revealed that these antibodies are probably the result of an oligoclonal B cell expansion.

Anti-La/SS-B are almost always found in combination with anti-Ro/SS-A. The reverse is not always the case: antibodies to Ro/SS-A often occur alone in SLE and systemic sclerosis (Table 3).

Classically, antibodies to Ro/SS-A and La/SS-B are detected by immunodiffusion and CIE. More recently, immunoblotting, ELISA and RNA precipitation have been used for the detection of anti-Ro/SS-A and anti-La/SS-B. Autoantibody levels against Ro/SS-A and La/SS-B in patients with SLE do not correlate with disease symptoms or activity. This is in contrast to anti-dsDNA activity which correlates very well with disease activity in these patients. This also implies that the anti-Ro/SS-A and anti-La/SS-B responses are regulated independently from anti-DNA. Anti-Ro/SS-A and anti-La/SS-B responses significantly correlate. Thus, most of the time anti-Ro/SS-A and anti-La/SS-B fluctuate together. One of the few clear-cut clinical correlations between an antinuclear antibody and a clinical syndrome is found in the congenital heart block (CHB). CHB was originally reported as a rare but potentially fatal complication of offspring from mothers with connective tissue disease, especially SLE. Maternal anti-Ro/SS-A are the largest single risk factor for the development of intrauterine or neonatal complete heart block in a child. The period of pregnancy when cases of fetal bradycardia are first noted (from the 20th week of gestation) coincides with the start of transplacental immunoglobulin G (IgG) transport. The autoantibodies are thought to mediate disease by eliciting an inflammatory reaction in the conduction tissue of the fetal heart. Parameters that would allow discrimination between 'pathogenic' (i.e. CHB-inducing) and nonpathogenic anti-Ro/SS-A have not yet unequivocally been identified.

Anti-rRNP

These antibodies react with the ribosomal phosphoproteins P1 and P2. Mostly, they also recognize the neutral phosphoprotein P0 (38 kDa) that is found in the large subunit of the ribosome.

Anti-P can be found in 10% of patients with SLE (Table 3). Initially, its occurrence was related to the presence of lupus psychosis, but later studies have not been able to confirm this relation. Anti-P can be readily detected by CIE and immunoblotting. In the latter assay, anti-P reactivity generally gives rise to three stained bands. Anti-P reactivity can also be detected using an ELISA in which a synthetic peptide of the C-terminal 22 amino acids serves as antigen. Longitudinal studies of anti-P in SLE have shown that quantitative determination has no practical value in the follow-up of SLE patients.

Anti-Jo1 and other anti-tRNA synthetases

Antibodies to tRNA synthetases often occur in patients with polymyositis. The best known of these ANAs is anti-Jo1, which is found in 30% of the patients with adult polymyositis (Table 3). The antibody is directed to the histidyl-tRNA synthetase (54 kDa). Anti-Jo1 can be detected by CIE, immunoblotting and specific ELISA. Because the synthetase is associated with a tRNA molecule, RNA precipitation results in a tRNA band upon gel electrophoresis.

Antibodies related to anti-Jo1 are anti-PL12, which is directed to alanyl-tRNA synthetase (110 kDa), and anti-PL7, directed to threonine-tRNA synthetase (80 kDa). Antibodies reactive with isoleucine-tRNA synthetase and glycine-tRNA synthetase have also been reported.

Concluding remarks

It is the current view that autoantigens themselves drive the autoimmune response against them. In that view, nucleosomes are to be considered the relevant autoantigen for the genesis of antibodies to nucleosomes, histones and DNA. Indeed, it would not be expected that DNA occurs freely in the circulation or the organs of the immune system, since in the nucleus of the cell it is so tightly bound to the core histones. Evidence implicating the role of nucleosomes as the driving antigen has been obtained by several different groups. Datta and colleagues, studying the role of T cells in the induction of autoantibodies, found that in lupus mice 50% of the pathogenic T helper cells respond to nucleosomes. These nucleosome-specific T helper cells not only induced the production of nucleosome-specific autoantibodies by syngeneic B cells, but also the formation of

anti-DNA and antihistone. Comparable results were obtained in studies with human T cell clones. These observations assign a central and dominant role to the nucleosome in the induction of the ANA response. The validity of this concept is underlined by observations made by Rubin and colleagues, that the formation of antibodies to nucleosomes precedes the development of anti-DNA and antihistone in MRL/lpr mice ('antigen spreading'). Sequencing of ANAs has taught us that ANAs, just like 'ordinary' antibodies show somatic mutations with increasing antibody avidity. This too, is taken as evidence for a driving role of the (auto)antigen in the immune response towards autoantigens.

ANTI-OXIDANT MICRONUTRIENTS AND THE IMMUNE SYSTEM

Adrianne Bendich, Human Nutrition Research, Roche Vitamins and Fine Chemicals, Paramus, New Jersey, USA

In the last decade there has been growing evidence that oxidative stress impairs immune responses and that anti-oxidants can reduce many aspects of oxidant-mediated immune suppression. Oxidative stress is directly related to the concentration of highly reactive molecules, most of which contain reactive species of oxygen, which reduce the anti-oxidant capacity of the body's cells.

Free radicals, highly reactive molecules with one or more unpaired electrons, often contain reactive oxygen species. Free radicals are generated during cellular metabolism, can be ingested or inhaled as environmental pollutants, or can be generated during the metabolism of certain drugs or xenobiotics.

Essential micronutrients with anti-oxidant activities

Antioxidants interfere with the production of free radicals and/or inactivate them once they are formed. There are four enzymes which have anti-oxidant capacity and contain essential minerals. These include two types of superoxide dismutases: a manganese-containing enzyme and an enzyme containing both copper and zinc. The third enzyme, catalase, an iron-containing enzyme, catalyzes the decomposition of hydrogen peroxide. Selenium is an essential component of the fourth enzyme, glutathione peroxidase, important in the decomposition of hydrogen peroxide and lipid peroxides, termination products of free radical attack on lipids.

Three other essential micronutrients can directly interfere with the propagation of, as well as scavenge, free radicals. Vitamin E (α -tocopherol), the major lipid-soluble anti-oxidant present in all cellular membranes, protects against lipid peroxidation and prevents the loss of membrane fluidity. Vitamin E has been characterized as the most critical anti-oxidant in blood. Vitamin C (ascorbic acid) is water soluble and, along with vitamin E, can quench free radicals as well as singlet oxygen. Ascorbate can also regenerate the reduced, anti-oxidant form of vitamin E. Recent work has shown that β -carotene, a pigment found in many photosynthetic plants, is an efficient quencher of singlet oxygen and can function as an anti-oxidant. β -Carotene is the major dietary carotenoid precursor of vitamin A. Vitamin A cannot quench singlet oxygen and has less anti-oxidant activity than the other nutrients discussed; however, its importance for the immune system is well recognized.

Assessment of oxidative stress and anti-oxidant status

Noninvasive measures

The most commonly used noninvasive measure of oxidative stress is the determination of the concentration of the volatile lipid oxidation products, pentane and ethane, in the breath. Dietary recall is the most commonly used noninvasive measure of intake of anti-oxidants.

Invasive measures

Serum concentrations of lipid peroxides and other oxidative products of proteins, DNA and carbohydrates are used to assess levels of oxidative stress. Serum concentrations of the anti-oxidant micronutrients are used as indicators of *in vivo* anti-oxidant status.

Free radicals and immune cell function

There are numerous links between free radical reactions and immune cell functions. White blood cell membranes are composed of lipids containing saturated and unsaturated fatty acids. Unsaturated bonds in fatty acids are highly susceptible to free radical attack, one consequence of which is to adversely affect the integrity of the cell membranes. For instance, oxygen-containing radicals and the products of their reactions have been shown to decrease the fluidity of white blood cell membranes and synovial fluids, consequently reducing their function.

Effects of immune-generated oxidants

The most abundant circulating white blood cell, the neutrophil, utilizes reactive oxygen species to kill invading organisms. When stimulated, neutrophils have the capacity to take up molecular oxygen and generate oxygen-containing free radicals and other reactive molecules. This is often called the oxidative burst. Free radicals and singlet oxygen, along with other reactive molecules, can kill pathogens. Neutrophils can also generate highly toxic halogenated molecules (e.g. hypochlorous acid) when the myeloperoxidase halide enzyme system is activated during the oxidative burst. The halogenated species can also lyse the phagocytosed pathogen. Recently, another reactive oxygen species, peroxynitrite, has been identified as an important component in immune cell killing of pathogens.

Under normal circumstances, the reactive oxygen species generated by neutrophils and other immune cells are used for control of infection; however, in circumstances of chronic activation the reactive oxygen products can result in destruction of normal tissue, as seen in rheumatoid arthritis.

Effects of anti-oxidant deficiency

One of the most obvious factors that could reduce anti-oxidant status is an induced dietary deficiency of, for instance, vitamin C. The effects of marginal vitamin C deficiency on immune and other parameters have been determined under highly controlled conditions in healthy males. Serum, white blood cell and sperm vitamin C levels were significantly reduced when the diet contained 5–20 mg of vitamin C for 2 months. Delayed-type hypersensitivity (DTH) responses were significantly depressed during the period of low vitamin C intake.

In addition to DTH responses, an index of oxidative damage to sperm DNA was also measured; these levels were significantly increased when vitamin C intakes were low. This carefully controlled study clearly demonstrated the importance of the balance between anti-oxidant status, oxidant levels and immune response. The study is especially noteworthy since all other dietary anti-oxidants, such as vitamin E and β -carotene, were provided throughout the study at recommended daily allowance (RDA) levels.

Clinical examples of free radical, anti-oxidant and immune function interactions

Examples of immune dysfunction associated with increased oxidative stress exemplify the interactions between the immune system and the oxidant/anti-oxidant status of the individual.

Rheumatoid arthritis

Rheumatoid arthritis (RA), an autoimmune disease of unknown cause, is characterized by a chronic inappropriate immune response in articular joints, resulting in inflammation and destruction of joint tissues. At some point, the initial insult and inflammation becomes a chronic process. Infiltration of the fluid-filled joint space (synovium) with inflammatory neutrophils occurs and structural changes appear in the synovium, forming an inflamed layer called a pannus. Oxidative products reduce the viscosity of the synovial fluid, thus hindering joint movement further.

Animal models have documented the increased production of pentane in arthritic animals; vitamin E supplementation lowered the pentane exhalation as well as joint swelling. Breath pentane concentrations correlates with the severity of symptoms in RA patients and clinical improvement is associated with a significant decrease in breath pentane. Patients with RA have significantly lower values in the total radical-trapping anti-oxidant parameter ('Trap') assay, based on serum levels of anti-oxidant nutrients, than do control subjects.

With regard to intervention studies, vitamin E has been examined to the greatest extent in patients with RA and other arthritic conditions. Three studies in RA patients suggest that vitamin E at high levels, but not at dietary intake levels, reduced pain. Vitamin E supplementation produced significant pain relief in four other studies. There was also a consistent finding of vitamin E-related antiinflammatory activity, although the studies involved a limited number of subjects.

Aging

The cumulative effects of free radical damage throughout the lifespan are seen in the pigmented age spots of the elderly, which are a consequence of lipid oxidation. The overall increased oxidative stress associated with aging also adversely affects many aspects of immune responses. The consequences of suboptimal immune responses are particularly detrimental in the elderly who have an increased risk of infections as well as of autoimmune diseases.

The cell-mediated immune responses involving T lymphocyte functions (cytotoxicity, interleukin 2 (IL-2) production, proliferation) are the most sensitive to the age-related decline in immune responses. As a consequence, DTH responses to skin test antigens are diminished in the elderly, and can often result in complete loss of response to antigen challenge (anergy) in the most immunosuppressed. Clinical studies have shown that DTH can be used as a pre-

dictor of morbidity and mortality in the elderly; i.e. elderly with anergy had twice the risk of death from all causes as elderly who responded to the antigens. Moreover, in hospitalized elderly who had undergone surgery, anergy was associated with a greater than tenfold increased risk of mortality and a fivefold increased risk of sepsis.

Recently, in a placebo-controlled study, intake of a one-a-day type multivitamin/mineral supplement for 12 months significantly enhanced DTH in healthy elderly. Because the multivitamin included β -carotene, vitamin E, vitamin C and all other essential vitamins as well as several minerals, it is not possible to determine whether the anti-oxidants or the other components in the multivitamin supplement were responsible for the improved DTH responses. In another recent placebo-controlled intervention trial, elderly were given a multivitamin, daily for 1 year, which contained approximately eight times the standard level of intake of β -carotene as well as higher levels of vitamins C and E. The supplemented group had significantly less infections than the placebo group. Responses to vaccines were also improved in the supplemented group.

With respect to individual anti-oxidants, an epidemiological study in an elderly population found that the higher the plasma vitamin E levels, the lower the number of infections. Two placebo-controlled, double-blind studies showed that vitamin E supplementation alone significantly enhanced DTH responses and/or T cell proliferative responses in the elderly. Lymphocyte vitamin E levels increased over threefold with supplementation and were correlated with enhanced IL-2 production and decreased prostaglandin E_2 as well as decreased serum lipid peroxides.

Cigarette smoking

Approximately 30% of US adult women and 25% of adult men smoke. Cigarette smoke contains millions of free radicals per inhalation. Other harmful products in cigarette smoke can stimulate the formation of highly reactive molecules that further increase the free radical burden; smokers have significantly higher breath pentane levels than nonsmokers. The micronutrient most affected by cigarette smoking appears to be the anti-oxidant, vitamin C. Smokers require about four times as much vitamin C per day to reach the same blood levels as nonsmokers. In addition to vitamin C, serum levels of vitamin E, folic acid and β -carotene, as well as lung vitamin E concentrations, are significantly lower in smokers compared to nonsmokers.

Cigarette smokers have depressed immune responses compared to nonsmokers, which may in

part be due to the overproduction of immunosuppressive free radicals by neutrophils and macrophages in their lungs. The lung of the healthy non-smoker contains very few neutrophils. In smokers, there is a constant activation of neutrophils and a consequent overproduction of reactive oxygen species.

Supplementation with high levels of vitamin E resulted in a significant decrease in smoker breath pentane levels and significantly reduced the overproduction of oxidant radicals by their circulating phagocytic cells.

Summary

Immune function is dependent upon a balance between the free radical and anti-oxidant status of the individual. In healthy adults, exposure to high levels of oxidants is associated with reduction in clinically relevant immune responses; exposure to low levels of dietary anti-oxidants also reduces immune responses such as DTH.

Anti-oxidant status becomes particularly critical in conditions which result in increased oxidative stress and immune dysfunction, as illustrated in RA, aging and cigarette smoking. In all three examples, evidence of free radical damage to lipids and other cellular components has been demonstrated. At the

same time, anti-oxidant status is reduced in arthritic patients and smokers compared with controls. Data suggest that elderly individuals may require higher levels of anti-oxidants to maintain DTH responses.

Several clinical studies have reported that supplemental anti-oxidants reduced indices of oxidative stress and improved various parameters of immune function.

ANTIBODIES: ANTIGENICITY OF

Felix Milgrom, Department of Microbiology, State University of New York at Buffalo, New York, USA

The term anti-antibodies (AAs) refers, in a broad sense, to all antibodies combining with other antibodies, the latter acting as antigens. This also includes antibodies against immunoglobulins of unknown antibody specificity. As early as 1900, Ehrlich and Morgenroth theorized about the formation of 'true AAs' directed against antibody-combining sites and postulated that such antibodies may exert a homeostatic mechanism preventing the formation of autoantibodies that could be harmful for the host. Subsequently, since the beginning of the twentieth century several investigators performed immunization of animals with antibodies of foreign species origin, with the objective of obtaining true AAs. All these studies, however, resulted in production of AAs directed against immunoglobulin structures other than the antibody-combining sites.

AAs to native antibody molecule other than the combining site

Moreschi (1909) used AAs to achieve agglutination of erythrocytes sensitized by nonagglutinating antibodies. He showed that rabbit erythrocytes sensitized by such antibodies of goat origin would undergo agglutination when exposed to rabbit antiserum against goat serum proteins. This was the first description of what has been called later antiglobulin reactions which were introduced into routine laboratory practice by Coombs, Mourant and Race in 1945. AAs active in these tests, frequently referred to as antiglobulin antibodies, are usually produced by immunization with immunoglobulins of animals of foreign species (e.g. rabbits or goats are immunized with human immunoglobulins). These AAs

recognize clearly the species origin of the antibody with which they are reacting.

Allotypes are inherited antigens of immunoglobulins originally described by Grubb (1956). They are usually recognized by means of AAs produced by an animal of the same species. Production of such AAs occurs spontaneously in some humans, although the reasons for this are unclear, or may be achieved by intentional immunization of animals, e.g. rabbits, mice or sheep with allogeneic immunoglobulins.

AAs to altered antibody molecules

Rheumatoid factor (RF) was described by Waaler in 1940 and by Rose and his associates in 1948. It was found in sera of a majority of patients with rheumatic arthritis; it combined with rabbit antibodies sensitizing sheep erythrocytes and caused agglutination of these erythrocytes. In the second part of the 1950s, a general consensus was reached among workers in the field that RF detected in sera of patients with rheumatoid arthritis is an antibody of the immunoglobulin M (IgM) class combining with the Fc fragment of IgG originating from a variety of species; the most frequently studied IgGs were of rabbit and human origin. It was shown that RF reacting with rabbit IgG is different from RF reacting with human IgG and that there also exists a cross-reacting RF, presumably a multispecific antibody combining with IgG of both of these species. Later, in addition to IgM, RF was shown in the IgG and IgA classes. The heterogeneity of RF justified the use of the plural – RFs.

Some investigators have referred to all RFs as autoantibodies. This does not seem justified at all with reference to the RFs combining with IgG of foreign species. Furthermore, RFs combining with human IgG frequently react only with aggregated IgG or, otherwise, with IgG of the allotypic specificity other than that of the patient. Again, neither of these RFs should be called an autoantibody. The term autoantibody should be reserved for those RFs that react with the patient's own native IgG; some evidence for the existence of such RFs has been presented.

An important observation concerning specificity of RFs was made by Hannestad and his associates in the 1970s. They demonstrated RFs which in addition to IgG reacted with other unrelated antigens such as nuclear antigens or cardiolipin. Significantly, the same molecule of RF could react with IgG and these unrelated antigens. It has been proposed that such a cross-reacting RF molecule recognizes shared epitopes on these antigens; alternatively, it has been suggested that the cross-reacting RF is a multispecific

antibody with separate or overlapping combining sites for different epitopes.

Another type of serum factor was described by Milgrom, Dubiski and Wozniczko in a few samples (less than 1%) of human sera in 1956. Similar to RFs, it is an IgM antibody combining with IgG antibodies, however this factor reacts only with human antibodies and only if they appear in the form of immune complexes; it does not react with free antibodies. Accordingly, this factor provided evidence for the long disputed thesis about molecular transformation of an antibody molecule in the course of its reaction with the antigen. Furthermore, the characteristics of this factor encouraged the hypothesis that this factor as well as RFs are formed in response to a stimulus exerted by the individual's own IgG antibodies altered during *in vivo* reactions with their antigens. According to this hypothesis, RFs as well as other AAs in human sera would represent stereotypes of reactions of subjects exposed to prolonged immunizing stimuli. This was consistent with the demonstration of RFs in several pathologic conditions other than rheumatoid arthritis, primarily in subacute bacterial endocarditis. This hypothesis was further supported by studies on experimental animals, which showed that immunization with partially denatured autologous IgG as well as prolonged exposure to any strong antigen resulted in formation of RF-like antibodies. Alternatively, several investigators postulated that RF may be formed as a result of polyclonal stimulation of B cells by mitogens released or created under various pathologic conditions.

The pathological role of RFs in rheumatoid arthritis has been repeatedly suggested but never substantiated convincingly. In recent years, more and more studies have been conducted on IgG RFs. It has been shown that these RFs have a propensity for self-aggregation in that each RF molecule may act as an antigen through its Fc fragment and as an antibody through its Fab fragment. Evidence has been obtained that such aggregates may form immune deposits responsible for or contributing to glomerulonephritides.

AS to the antibody-combining sites

As mentioned, early attempts to elicit production of true AS met with failure. Immunization with antibodies originating from a species foreign to the immunized animal resulted in formation of AS of antiglobulin nature. In 1957, however, immunization of rabbits with rabbit antibodies to *Proteus* and *Escherichia* was shown by Milgrom and Dubiski to result in the formation of AAs that distinguished

the anti-*Proteus* from the anti-*Escherichia* antibody and accordingly, appeared to have properties of true AAs. Subsequently, in 1963 Kunkel, Mannik and Williams as well as Oudin and Michel, used various protocols of immunization of animals and succeeded in eliciting formation of what appeared to be true AAs. They called them idiotypic antibodies. Further studies, however, showed that the idiotypic specificity cannot be equated with the structure of the antibody-combining site, even if it is closely related to this structure.

ANTIBODIES, BISPECIFIC

Constantin A Bona, Department of Microbiology, Mount Sinai Medical School, New York, USA

Bispecific (bifunctional) antibodies represent a category of artificially created immunoglobulins exhibiting a double, well-defined antigen specificity. The major application of bispecific antibodies is to focus the activity of an effector cell on a target cell by virtue of their ability to bind with one combining site to effector cell and with another to target cells.

Antibodies against the T cell receptor (TCR) of helper and cytotoxic effector cells are able to mimic the antigen and to activate the T cells to proliferate, to release lymphokines or to become cytotoxic. Bispecific antibodies which bind with one arm to the effector cell and with another to the target cell can activate the effector cell and ensure intimate contact between effector and target cells.

The preparation of bispecific antibodies was helped by the development of monoclonal antibody technology which can provide unlimited amounts of homogeneous antibody. There are three basic methods used to prepare bispecific molecules with 'à la carte' desired specificity (Figure 1).

Heteroconjugates

Heteroconjugates are bispecific antibodies obtained by chemical linkage of two immunoglobulin (Ig) molecules with different binding specificity. The chemical linkage of two monoclonal antibodies is carried out using cross-linkers such as *N*-succinimyl-3-(2-pyridyldithio)-propionate (SPDP). High-pressure liquid chromatography (HPLC) is used for the purification of heteroconjugates made up of only dimers.

In vitro experiments demonstrated that such heteroconjugates are able to focus the activity of effector T cells on target cells bearing different antigen specificity. The presence of monocytes which can bind the heteroconjugates via Fc receptor can supply additional signals for the activation of T cells. It remains to be tested whether these antibodies are effective *in vivo*, in particular whether they could achieve the activation of local T cell contact with the target cells.

Heteroconjugates, although relatively easy to produce, are likely to be cleared quickly and may function as immune complexes, eventually causing immunopathological phenomena *in vivo*. Their stab-

Figure 1 Structural characteristics and binding properties of various types of bispecific antibodies.

ility *in vivo* is questionable and since they are dimeric molecules they can cause antigenic modulation subsequent to cross-linking of TCR molecules associated with the surface of effector cells or of antigen molecules expressed on the surface of target cells.

Quadroma bispecific antibodies

Quadromas are bispecific antibodies synthesized by hybrid hybridomas obtained by fusion of two lymphocytes producing antibodies with different specificity. Because in hybrid hybridomas the expressed V_H and V_K genes of the parental cells are all produced there are ten molecular species of hybrid antibodies which theoretically can be formed as expected from the random association of the product of each gene. However, immunochemical studies of Ig mol-

ecules produced by quadromas showed that only six species were secreted and indicated a marginal preference for heavy-light chain homologous combination. The theoretical yield of a bispecific antibody with desired specificity produced by quadromas is 8–17% of the total Ig synthesized.

The production of quadromas is based on the principle of fusing two parental cells, each carrying a different drug resistant marker and selecting the hybrids of both type of cells in the presence of both drugs.

There have been only a few successful attempts to produce quadromas by fusing cells sensitive or resistant to various drugs such as hypoxanthine-aminopterin-thymidine (HAT)-sensitive, ouabain-resistant, neomycin (G418)-resistant, or resistant to iodoacetamide damage. Utilization of these drugs requires tedious experiments to select drug-sensitive or -resistant mutants in the population of hybridomas which will be used to generate quadromas. A new and easier method takes advantage of defective retroviruses carrying genes conferring resistance to neomycin or methotrexate.

Each partner of the fusion is infected with a retrovirus which confers a stable drug resistance at a very high frequency. The yield of quadromas using retrovirus-infected cells is generally higher than those using cells sensitive or resistant to various drugs. Utilization of hybridomas producing antibodies with different isotypes or idiotypes facilitates the purification of bispecific antibodies using anti-isotype or anti-idiotypic immunoadsorbents.

Bispecific antibodies specific for the TCR of cytotoxic T lymphocytes (CTLs) and for viral antigens budding from the surface of target cells or against tumor antigens have been shown to be very efficient in small concentrations to focus CTL activity on target cells and to cause their lysis. The Fab fragment binding to the TCR is sufficient to activate the CTL, and the other Fab fragment brings the target cell in intimate contact with the CTL thereby causing lysis of the target.

It has been clearly shown that the redirected lysis mediated by bispecific antibodies circumvents the genetic restriction requirement of T cells. The efficacy of bispecific antibodies can be increased by preactivation of CTLs with specific antigens or superantigens. Bispecific monoclonal antibodies have numerous advantages when compared with chemically constructed heteroconjugates. These advantages include greater uniformity, stability and purity, and the absence of aggregates which may be cleared from the circulation as immune complexes. They also have a longer half-life *in vivo* because of their normal structure. In addition, because of the monomeric structure of the combining site it is unlikely that it

will cause antigen modulation, a phenomenon which requires cross-linking of receptors or antigens associated with the membrane of effector or target cells.

Bispecific molecules produced by genetic engineering

The development of molecular biology techniques provided a new approach which permits the insertion, within or adjacent to the genes encoding an immunoglobulin molecule, of oligonucleotides encoding another immunoglobulin, a desired immunogenic epitope or an epitope responsible for interaction with a viral antigen. For example, it is possible to create a bispecific molecule in which the coding sequence for the V region of a CD3-specific antibody is combined with the sequence for the CD4 molecule which is able to bind HIVgp120. Such a bispecific molecule could activate a CTL and bring it into intimate contact with an HIV-infected cell.

Bispecific antibodies and heteroconjugates have a potential application in antitumor therapy and in the treatment of infectious diseases caused by bacteria or viruses in which the microbial antigen is expressed on the surface of infected cells. In the case of antitumor therapy, a bispecific antibody could be constructed using a monoclonal antibody specific for the TCR-CD3 complex (i.e. anti-CD3, anti-idiotypic or anti-allotype) and a monoclonal antibody specific for a tumor-associated antigen. Bispecific antibodies have also been used to deliver isotopes or toxins to tumors which are difficult to remove by surgery or to tag remaining tumor cells after surgery. The efficiency of bispecific antibodies as antitumor immunotherapeutic agents are currently being evaluated in clinical trials in humans.

In the case of the treatment of infectious diseases the heteroconjugates or bispecific antibodies can be constructed using monoclonal antibodies against the TCR-CD3 complex of CTL and monoclonal antibody specific for a viral antigen. Evidence has been presented in a number of viral diseases that viral-specific CTLs reduce viral replication and dissemination. Therefore, the focusing of CTLs on virally infected cells by bispecific antibodies can prevent viral replication and spreading. It has already been shown that heteroconjugates or bispecific antibodies can redirect CTL activity against cells infected with

viruses such as human immunodeficiency virus (HIV), herpes or influenza.

Thus, it appears that bispecific antibodies have the potential to become a new category of immunotherapeutic reagents.

ANTIBODIES, DETECTION OF

Michael A Kerr, Department of Molecular and Cellular Pathology, University of Dundee, Ninewells Hospital Medical School, Dundee, Scotland
Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The widespread use of diagnostic tests which depend on the use of antibodies, together with the increasing use of antibodies in research laboratories for the detection and quantitation of all manner of biochemicals, has resulted in the development of a vast array of different techniques which can be used to detect antibodies. The nature, abundance and purity of the antigen recognized by the antibody and the number of assays to be performed will be the main factors which determine the selection of one technique rather than another. The most commonly used techniques and their relative advantages and disadvantages are summarized below.

Immunoprecipitation techniques

Antibodies were first detected by their ability to precipitate antigen when mixed at equivalence. This classical precipitin reaction of Heidelberger and Kendall is seldom used in its original form but precipitation tests adapted in many different ways are still widely used for the detection of antibody. In the double diffusion or Ouchterlony technique, antigen and antibody are placed in adjacent wells punched out of an agarose gel. Precipitation occurs when the two meet at appropriate concentrations. The simplicity of this technique makes it ideal for the initial screening of antisera raised in animals. Under appropriate conditions the test can also be used for comparing the specificity of antisera or determining the relatedness of two antigens. The test is commonly used for determining the class or subclass of monoclonal antibodies (in this case the monoclonal antibody is behaving as the antigen).

Many other techniques involving precipitation in gels are used primarily in the detection and quantitation of antigen. Counterimmunoelectrophoresis, in which the antigen and antibody are concentrated together by the effect of an electric current, is one modification of the Ouchterlony technique used for the detection of antibodies. Precipitation techniques are, in general, rather insensitive, detecting antibodies or antigens in the $\mu\text{g ml}^{-1}$ range. They are more useful for the detection of antibodies in polyclonal antisera rather than monoclonal antibodies which precipitate poorly.

The sensitivity of the basic precipitin reaction can be increased considerably by the use of complex optical detection systems to determine the amount

of precipitation. Highly sensitive turbidometers and laser-based nephelometers are widely available. Though the equipment is expensive, these techniques are commonplace in diagnostic laboratories where high throughput can justify the initial investment.

Precipitin reactions can be accelerated by the inclusion of suitable concentrations of reagents such as ammonium sulfate or polyethylene glycol which will encourage precipitation of antibody or antibody-antigen aggregates but not free antigen. If the antigen is radiolabeled, this can be used as a sensitive and simple test for the detection of antibody – the Farr test. Radioimmunoassays have been used extensively for many years for the quantitation of antigens such as hormones and drugs which are present in very low concentrations.

Agglutination assays

If an antigen is particulate, e.g. a bacterial surface antigen or eukaryotic cell surface antigen, agglutination of the cells by the addition of antibody can provide a simple detection system. Agglutination is the standard test for blood group serology and it has other specialized applications. The technique can be extended to antibodies against soluble antigens by coupling of the antigens to particulate carriers. Initially the carrier of choice was the erythrocyte and detection systems depended on coupling of antigen on to the red cell using tannic acid. Hemagglutination assays remain the basis of several diagnostic test systems, quantitation being possible in terms of the antibody dilution of titer at which agglutination stops.

A number of synthetic carriers have been developed, including latex particles and a new generation of polymerized gelatin particles. Agglutination assays are simple to perform, requiring little or no expensive equipment. Modern versions are very sensitive and highly suitable for use outside the laboratory and in less-developed countries. They are widely used for detection of antibodies in the diagnosis of infectious disease. Tests for the human immunodeficiency virus (HIV) based on agglutination techniques compare favorably with other techniques. One drawback is that the tests can be more sensitive to the detection of polymeric immunoglobulin M (IgM) antibodies. This can be advantageous in detecting recent infections but might

be a problem in autoimmune serology. Sensitivity can be down to $1 \mu\text{g ml}^{-1}$.

Complement-dependent assays

The lytic activity of complement can be used in sensitive tests for the detection of antibodies recognizing cell surface antigens. Although now of limited application, it is still used widely in certain specialized situations, for example, the detection of antibodies recognizing histocompatibility antigens. Complement-mediated cytotoxicity is detected either by dye exclusion or by the release of ^{51}Cr from labeled cells. Complement fixation tests, once widely used, depend on the fact that antibody-antigen interaction will consume complement and the remaining complement can then be measured in a hemolytic assay. Though sensitive, these assays have declining usage.

Detection of antibodies using labeled anti-immunoglobulin reagents

The most widely used tests are those which use a second antibody, labeled in some way, to detect the binding of primary antibody to antigen. The availability of excellent, highly specific reagents from many commercial sources has made these techniques simple to apply in any laboratory. 'Second antibodies' are available which recognize immunoglobulins from humans and from most laboratory and veterinary animals. The second antibody can be labeled with radioactivity (usually ^{125}I), a fluorescent or luminescent dye, or coupled covalently to enzyme molecules. Each type of assay has its own advantages and disadvantages.

In quantitative assays, the antigen is usually coated on to plastic tubes or, more frequently, 96-well microplates to provide a solid phase on which to capture antibody. Sensitive detectors measure enzyme activity colorimetrically or detect chemiluminescence or fluorescence in this format. Flexible plates can be cut up for counting radioactivity. The enzyme-linked immunosorbent assay (ELISA) is the most widely used technique. Bound antibody is usually detected using alkaline phosphatase, horseradish peroxidase or β -galactosidase-conjugated second antibody. All of these enzymes cleave suitable substrates to yield highly colored products allowing detection of antibody in the ng ml^{-1} range.

Blotting techniques

A variation on the ELISA involves immobilization of antigen on sheets of nitrocellulose or a similar carrier. Again, filtration devices in the 96-well format

give easy sample management. These 'dot blots' provide rapid, sensitive and simple tests with wide application in research laboratories. Enzyme-linked antibody systems are again most commonly used, utilizing the same conjugates as ELISA but substrates which give highly colored insoluble products. This allows easy measurement by eye, with the option that reflectance readers can be used for quantitation in a manner analogous to conventional ELISA readers. Related blotting techniques are used increasingly in rapid diagnostic tests. Most 'dipstick' techniques use this approach. Purified or recombinant antigens can be coated easily on to plastic or cellulose matrixes as the support for these rapid tests. Several antigens can be applied as discrete spots or bands to allow differential detection of specific antibodies in the same sera; ideal for many applications in infective or autoimmune serology.

In the research laboratory, the immunoblot or western blot is one of the most widely used techniques for the determination of antibody specificity. Separation of a complex mixture of antigens, for example a cellular extract, on polyacrylamide gels is followed by transfer of the separated proteins to a rigid medium such as nitrocellulose or nylon. Antibody is then added and after washing, the blot is developed with labeled second antibody and substrate. This allows characterization of the specificity of an antiserum or monoclonal antibody at the molecular level. The major drawback is that many antigenic determinants are destroyed by the SDS and denaturants used in the electrophoretic procedure. Blotting techniques can also be used for detecting antibodies against glycolipid antigens.

Immunohistochemistry

When the antigen is cell-associated, immunohistochemistry allows the detection and characterization of antibodies. For tissue sections, immunofluorescence is favored in many laboratories because of its simplicity. It is particularly useful for the detection of antibodies, including autoantibodies, recognizing antigens in intracellular organelles or where double labeling with two different antibodies (detected using two dyes of different color) is advantageous. Fluorescein and rhodamine are the standard conjugates, but a wide range of different colored dyes are available. Laser-based confocal microscopes have greatly increased the sensitivity and specificity of these techniques.

Immunofluorescent techniques for the detection of antibodies are widely used in conjunction with the flow cytometer or fluorescence-activated cell sorter. CD numbers describe leukocyte cell surface antigens

recognized by monoclonal antibodies, defined initially by their cytofluorometric staining patterns on a large panel of different cell types. A wide range of different laser dyes are now available which are designed for use with the lasers commonly used in flow cytometers and confocal microscopes.

For tissue immunohistochemistry, enzyme-labeled antibodies are the choice in most laboratories. Peroxidase- and alkaline phosphatase-based techniques are used especially where the antigen detected will withstand the harsh fixation techniques often necessary to maintain tissue integrity. At the electron microscope level, immunogold techniques are used. Small, specifically sized gold particles are attached to antibody to allow localization of antigens. Colloidal gold conjugates can also be used successfully at the light microscope level, particularly in association with silver enhancement techniques. Immunogold can also be applied to blotting techniques giving sensitivity similar to that of enzyme-based detection systems.

Increasing sensitivity

Enzyme-based immunoassays, blotting techniques and immunohistochemistry have become the norm for the detection of antibodies and for characterization of their specificity. These systems have been developed in several ways to increase their sensitivity and ease of application. Biotin, a small molecule (244 Da) which binds with very high affinity to the proteins avidin or streptavidin, can itself be bound covalently to immunoglobulins without the loss of activity. A single biotinylated reagent can then be used in any test system with suitably labeled avidins. Since avidin can bind up to four biotin molecules, this gives the possibility of multilayered systems which offer increased sensitivity.

Alternative approaches to the detection of antibody utilize protein A, a bacterial surface protein which binds specifically to certain classes of IgG. Protein A in its natural or recombinant form or protein G, an IgG-binding protein from streptococci, are widely available. Protein G has broader specificity for subclasses of IgG and binds better to sheep and goat IgG than protein A. Second antibody systems do, however, remain the method of choice, particularly with the availability of good monoclonal antibodies specific for individual immunoglobulin classes or subclasses.

Although conventional detection systems are usually for sufficient sensitivity for the detection of antibodies, the detection of trace antigens such as growth factors or their receptors can require the necessity for an amplified detection system which will quantitate

the binding of a primary antibody. Increased sensitivity is possible by the use of sandwich techniques involving several layers of antibody, enzyme-antibody complexes, biotin-avidin complexes or by newly developed specific amplification systems. One example of an enhancement system uses alkaline phosphatase conjugated to the detecting antibody to generate NAD from NADP. The NAD is then used in a pair of cycling redox reactions to reduce a colorless precursor to a colored formazan dye. The reaction product can be detected at 492 nm by conventional readers. The amplification step results in an increase in sensitivity of over 100-fold and is the basis of several rapid dipstick-type tests.

Chemiluminescence-based techniques have replaced colorimetric ELISAs and immunoblotting techniques in many laboratories because of their much greater sensitivity. A number of substrates which yield chemiluminescent products upon cleavage by peroxidase (luminol) or alkaline phosphatase (dioxetane phosphate esters) are available, usually in the form of kits containing all necessary reagents. For ELISA-based assays 96-well microplate luminometers are used. In chemiluminescence-based blotting techniques the signal can be detected using photographic film or specially designed plate detectors.

Time-resolved fluorescence techniques such as the DELFIA (Pharmacia) system, have been developed to replace the radioimmunoassay for the measurement of hormones etc. in large diagnostic laboratories. These assays are equally applicable to detection of antibodies, for example, in the diagnosis of infectious diseases. DELFIA utilizes Europium³⁺ bound to proteins through a covalently-linked EDTA derivative. Excess of the chelators naphthoylethyltrifluoroacetone and trioctylphosphine are then used to form a fluorescent complex in solution at low pH.

Future advances

Techniques developed for the detection of antibodies during the last few decades have sufficient sensitivity, diversity of application and robustness that they serve the vast majority of requirements. The widespread availability of highly specific, conjugated second antibodies and novel detection systems means that major gains in sensitivity are not necessary for the detection of most antibodies. It is advances in speed and ease of application which will determine the tests of the future. To this end, it is important to appreciate the potential of the instantaneous electrochemical tests based on biosensors and microelectronics which are already being developed and could

make the detection of antibodies as simple and quick as the measurement of pH.

ANTIBODIES, SECRETION

Roberto Sitia, DIBIT – San Raffaele Scientific Institute, 20132 Milan, Italy

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

As established by the classical experiments of Palade and coworkers, proteins destined to be secreted (as well as cell surface proteins) are synthesized in the endoplasmic reticulum (ER), and then transported through the Golgi complex to the extracellular space. Distinct post-translational modifications (assembly, glycosylation, etc.) take place sequentially along this pathway, allowing the intracellular location of a protein to be determined. The stepwise nature of the secretory pathway is confirmed by the existence of drugs which block intracellular transport at given stages. Similarly, several yeast temperature-sensitive mutants have been characterized in which secretion is blocked at different levels. Since mutations or drugs block the export of most secretory proteins, there appears to be only one main secretory pathway, utilized also by proteins destined to be expressed on the plasma membrane. An alternative pathway has been identified, which allows the selective secretion of certain cytosolic proteins lacking a conventional 'signal sequence' (see below).

Antibody secretion will be discussed in the context of the general problems of protein secretion. Among the many exciting questions in this field, the ones related to selectivity are maybe the most intriguing. How do cells decide what to secrete, when, and for how long?

Antibodies as a model system for protein secretion

Like all proteins destined to be synthesized in the ER,

immunoglobulins are characterized by an N-terminal stretch of hydrophobic amino acids, the signal (leader) sequence, first inferred by Milstein and coworkers in 1972 in studies on immunoglobulin (Ig) light chain secretion. The signal sequence interacts with a multimeric ribonucleoprotein, the signal recognition particle (SRP). This interaction arrests translation until the complex formed by ribosome, nascent protein and SRP binds to the SRP receptor or docking protein on the ER membrane. Translocation of the nascent chain across the ER membrane occurs cotranslationally and the signal sequence is then cleaved by specific proteases located on the luminal face of the ER membrane. The first steps of N-linked glycosylation also occur cotranslationally (Figure 1).

The signal sequence is a paradigmatic example of 'positive' sorting: only the proteins that express it enter the secretory pathway. However, not all proteins synthesized within the ER will reach the extracellular space: some of them accumulate in the ER, some in the Golgi. Specific C-terminal sequences have been shown to cause *retention* within the ER of the proteins possessing them. This has led to the proposal of the bulk flow model, according to which all proteins in the secretory compartment will be secreted 'by default' unless they are marked with specific 'retention signals' which block them within a given organelle.

Protein secretion may be constitutive or regulated. Antibodies are secreted by plasma cells through the constitutive pathway. In the regulated pathway, pro-

Figure 1 Assembly and secretion of immunoglobulins. The N-terminal signal sequence (ss) is recognized by the signal recognition particle (srp) on cytosolic nascent proteins. This interaction causes an arrest in translation (–). The complex binds to the srp receptor (or docking protein, srp-r), targeting the ribosome to the ER membrane, and allowing elongation of the nascent polypeptide (+). Translocation of the ER membrane and the first steps of N-linked glycosylation (addition of the $\text{GlcNac}_2\text{Man}_9\text{Glu}_3$ precursor) occur cotranslationally. Folding and assembly begin when the nascent H and L chains are still on the polysome, and are rapidly completed under the assistance of ER chaperones and folding enzymes (BiP, calnexin, PDI, ERp72, etc.). Only fully assembled molecules are transported to the Golgi, where they undergo terminal processing of their sugar moieties (*) before being released into the extracellular space. Folding and assembly intermediates are retained in the ER, or retrieved in this organelle from the early compartments of the cis Golgi network. A proteolytic system, independent from that of lysosomes, maintains homeostasis in the ER. All transport steps occur within membrane-sealed vesicles that are thought to bud from one compartment and fuse with the next along the exocytic pathway.

teins are concentrated within intracellular stores (secretory granules) and bursts of secretion can be triggered at rates much higher than the synthetic one. In constitutive secretion there is normally little intracellular accumulation, and secretion depends largely on the rate of synthesis. However, IgM antibodies are an exception to this scheme as their secretion is developmentally regulated (see below). Constitutive secretion is common to virtually all cells, although at different levels. Like most cells specialized in secretion, plasma cells have abundant ER and a developed Golgi apparatus. By contrast, B cells have a very scarce ER.

Secreted proteins are remarkably uniform, and *only* fully assembled molecules are released extracellularly. This selectivity implies the existence of quality control steps in protein synthesis, folding and assembly, which appear to be coupled to intracellular transport. In addition, to maintain cellular homeostasis, proteins which fail these editing steps, and are hence not transported, must be degraded. Antibodies are an excellent model for understanding how cells manage to obtain high secretion efficiency and stringent quality control of the released products. This will be of interest in the general context of protein secretion, as well as for some more specific problems, namely how the onset, duration and intensity of the antibody responses are controlled.

Antibody secretion during B cell differentiation

Before it was discovered that membrane and secreted Ig contained distinct forms of heavy chains, differing at their C-termini, the problem of the differential expression of Ig during B cell differentiation was a dilemma for both immunologists and cell biologists. It was known that small, resting B lymphocytes expressed IgM on the cell surface (10^4 – 10^5 molecules per cell), but did not secrete IgM molecules. The same cells can be induced by mitogens or antigen to differentiate into plaque-forming cells (PFC), which lack surface Ig and secrete large amounts of antibodies (over 10^3 copies s^{-1} per cell). Since it was thought that constitutive secretion could be regulated only by changing the rate of synthesis, it was not easy to explain these results. In 1978–1981 it became clear that μ chains, as well as all other heavy chain isotypes, may be produced in a membrane (μm) or a secretory (μs) form by alternate RNA processing. The $\mu\text{m} : \mu\text{s}$ ratio varies during B cell differentiation, μm predominating in the early (pre-B, B cells), and μs in the late stages (activated B cells and plasma cells). However, in many B lymphomas, abundant μs mRNA is present, and the rate of synthesis and assembly to light (L) chain is quite similar for μm and μs , indicating that the block in IgM secretion is

due to post-translational mechanism(s). The molecular mechanisms preventing IgM secretion in B cells are related to the general problem as to how cells make sure that only fully assembled molecules are secreted or expressed on the cell surface, and will be discussed below.

Only fully assembled immunoglobulins are secreted

Antibodies are multimeric glycoproteins, made of two L and two heavy (H) chains. To maintain the clonal organization of the immune system, allelic exclusion ensures that only one H and one L chain specificity are produced by a B lymphocyte. However, the specificity of a V_H region might differ if H chains were not assembled with L chains. The mechanisms ensuring that only the fully assembled forms of antibody molecules are secreted by plasma cells (or expressed on the surface of B lymphocytes) have been understood recently, and once again information gathered on antibodies has proven of general relevance. It has been shown that, in the absence of L chains, H chains interact with BiP (heavy chain binding protein, grp 78), an abundant resident protein of the ER. BiP belongs to the protein family of chaperonins, which, together with oxidoreductases (such as PDI or ERp72) and other enzymes, assist the folding and the assembly of newly synthesized proteins in the ER. Since BiP is itself retained in the ER lumen via its C-terminal sequence Lys-Asp-Glu-Leu (KDEL), unassembled H chains are not able to leave the ER. The interaction with BiP involves the first constant domain of the H chain (C_{H1}), which normally interacts with the constant domain of L chains. Thus, assembly with L chains masks the BiP binding site, allowing assembled molecules to exit the ER and reach the Golgi apparatus, where terminal glycosylation takes place (Figure 1). Deletion of the C_{H1} domain by recombinant DNA techniques allows secretion of free γ heavy chains, a finding that explains why, in the rare cases of heavy chain disease, secreted free heavy chains always lack the C_{H1} .

Developmental control of IgM secretion

In the case of IgM and IgA, the basic H_2L_2 structure is further assembled into polymers which contain J chain, a small cysteine-rich glycoprotein synthesized by plasma cells, but not by resting B lymphocytes. Only polymeric IgM is secreted, despite the fact that the major intracellular form is μ_2L_2 . Thus, IgM (and IgA) undergo a further level of control, which blocks secretion of nonpolymeric molecules. This editing step depends on disulfide interchange reactions,

which involve the cysteine residue found at the penultimate position of both μ_s and α_s chains. This residue is responsible for the intersubunit disulfide bonds which stabilize the polymeric structure. In assembly intermediates the unbound SH group may interact with ER resident proteins, thereby blocking their transport to the Golgi. Thus, IgM is subject to a dual editing process which allows plasma cells to secrete only polymers. First, μ -L association is controlled by interactions between BiP and sequences in the $C_{\mu 1}$; then, disulfide interchange reactions control polymerization.

In B lymphocytes, polymerization is very inefficient, a finding that explains why IgM is not secreted. The requirement for polymerization might also explain why, also in myelomas, secretion of IgM is rather slow and inefficient compared with IgG. If the C-terminal cysteine of the μ_s chain is replaced by serine, the rate and efficiency of IgM secretion is increased, and intracellular degradation reduced. Furthermore, these mutant monomeric IgMs are secreted also by B cells, indicating that the presence of a developed ER is not *per se* necessary for secretion of immunoglobulin molecules.

As polymeric IgM contains J chains, it has been proposed that the failure of B cells to secrete IgM correlates with the absence of J chain synthesis. However, since B cell lines have been isolated which synthesize J chain and yet do not secrete IgM, and nonlymphoid transfectants secrete polymeric IgM lacking J chains, the latter appear to be neither essential nor sufficient for IgM secretion. Knock-out mice that lack J chains have high levels of IgA (mainly monomeric) and of hexameric IgM in the serum. Hence, J chain seems to play a key role in 1) determining the size of polymeric IgM (pentamers predominate in the presence of J chain), and 2) facilitating the transcytosis of polymeric Igs across epithelia. The problem of why B cells do not secrete IgM may thus be reduced to the single question as to why in B cells polymerization is so inefficient. Differentiation into IgM secreting plasma cells is accompanied by major changes in the ER and by a much higher rate of synthesis of μ and L chains. These events might include modification(s) of the redox potential along the secretory pathway which would favor polymerization.

Glycosylation and secretion

Despite the abundant literature on the issue, the precise function of the carbohydrate moieties of glycoproteins remains to be established. Selective inhibitors (e.g. tunicamycin) or site-directed mutagenesis of the relevant asparagines have been employed to

prevent *N*-linked glycosylation of many glycoproteins, including IgS. In those systems where the presence of tunicamycin blocks secretion, folding and assembly are slower, and intracellular degradation is increased. Glycosylation might increase solubility and stability of antibodies. Since many deglycosylated proteins are exported, glycosylation does not appear essential for secretion. However, the recent findings of several compartmentalized molecules with lectin activity within the secretory pathway have awakened the dormant hypothesis of a role of glycans in facilitating exocytosis.

Intracellular degradation of newly synthesized proteins

To maintain the steady state, proteins which cannot be secreted must be degraded. On the other hand, unassembled or misfolded proteins are retained in the ER via interactions with BiP or disulfide interchange reactions, and may thus not reach the lysosome. This apparent paradox was solved when it became clear that a proteolytic system, independent from the lysosomal one, exists in a pre-Golgi compartment. Heavy chains are degraded more rapidly when not assembled to L chains. Assembly might decrease the susceptibility to proteases, hide signals which target to degradation, or both.

The biochemistry of ER degradation is still largely unknown. Evidence has been recently obtained that ubiquitin and proteasomes are involved in the degradation of CFTR, a transmembrane protein retained in the ER in cystic fibrosis patients. As to the specificity of the process, in many cases, including T cell receptors and Igs, the signals that lead to degradation have been shown to coincide with those that mediate the assembly as well as the retention of unassembled subunits. However, there must be a lag while nascent proteins, that are bound to express many degradation targeting signals, are protected from proteolysis. A distinct subcompartment, specialized in proteolytic activity, may exist in the ER. Alternatively, nascent proteins maybe shielded by chaperones.

Pathologic conditions related to Ig secretion

Defects in immunoglobulin secretion might be at the basis of certain pathologic conditions such as common variable immunodeficiency (acquired hypogammaglobulinemia). In this disease, the number of membrane Ig-expressing B cells is normal but very little antibody is present in the serum: defects in γ chain glycosylation have been reported, but their pathogenic relevance remains to be established.

Immunodeficiency with hyper IgM is characterized by high levels of serum IgM and virtual absence of IgG and IgA. In these patients, mutations in the CD40 ligand perturb T cell-B cell interactions, resulting in impaired isotype switching and affinity maturation. Although it is worth recalling that considerable amounts of monomeric IgM are present in the serum of these patients, the significance of this observation is at present unclear.

Many observations on myelomas and heavy chain disease related to defects in or unbalanced Ig secretion have already been mentioned. Secretion of free L chains (Bence Jones proteins), does not appear to be a characteristic of neoplastic plasma cells, but probably reflects an important feature of the Ig assembly line, where the limiting factor is the heavy chain. While cells producing only L are frequent, myeloma mutants producing only H are exceedingly rare, an observation which led to the proposal of heavy chain toxicity. Assembly of complete Ig molecules requires an equal number of L and H chains. Although it might be thought more economical for the cell to synthesize equimolar amounts of the two chains, L chains are produced in excess to optimize HL assembly. The excess L chains can be secreted mainly as L₂ homodimers.

Mott cells are plasma cells defective in Ig secretion found in multiple myeloma and certain chronic inflammatory and autoimmune conditions. Mott cells are characterized by cytoplasmic inclusions normally containing immunoglobulin molecules, called Russell bodies, and representing dilated cisternae of the ER. Mott hybridomas have been obtained by fusing splenocytes from NZB mice, a strain highly susceptible to autoimmune diseases. Since these hybridomas express several membrane antigens, a general defect in the secretory pathway may be excluded. That the Mott cell phenotype is due to mutations in the Ig chains is indicated by the observation that Russell bodies are formed upon transfection of certain mutated heavy chains into myeloma cells. Not all nonsecretable chains induced the Mott phenotype. Thus, Russell bodies probably reflect the presence of nontransportable molecules resistant to pre-Golgi degradation.

Ig secretion by nonlymphoid cells

Immunoglobulins have been expressed in several heterologous systems, such as nonlymphoid transfectants, *Xenopus* oocytes, or transgenic plants. In most cases, immunoglobulin molecules were properly assembled and secreted. Mutants were handled similarly by lymphoid and nonlymphoid cells, and Russell bodies could be detected in glioma transfectants.

Thus, unlike the rearrangement of Ig genes, the complex and developmentally regulated processes of Ig assembly and secretion do not appear to require tissue-specific factors.

Secretory immunoglobulins

Antibodies in external fluids (milk, bile, saliva, lacrimal, nasal, intestinal, cervical fluids) are often called secretory Ig, as opposed to serum Ig, a definition that may generate confusion now that the same term is used to discriminate the soluble form from the membrane-bound form of antibody molecules. Polymeric immunoglobulins (IgM and IgA) in external secretions contain, in addition to J chain, a polypeptide of approximately 25 kDa, called the secretory component. The latter is not produced by lymphoid cells, but represents a portion of the poly-Ig receptor which is proteolytically cleaved during the process of transcytosis across epithelial cells.

ANTIBODIES, SPECIFICITY

Denong Wang and **Elvin A Kabat**, Department of Microbiology, College of Physicians and Surgeons, Columbia University, New York, USA

Quantitatively, the specificities of antibodies are determined by their relative binding affinities, the intrinsic property of each antibody combining site, expressed as equilibrium dissociation (K_d) or association constants (K_a) for their interactions with different antigens. The K_d values may vary significantly among different antibody–antigen interactions, ranging from 10^{-3} M to 10^{-11} M or higher, but never reach the value of the binding of biotin to avidin (K_d 10^{-15} M).

Different classes of antibodies may differ in their ‘avidities’, i.e. the number of combining sites on each antibody. As illustrated in Figure 1, an antibody molecule has a four-chain structure built of two identical heavy (H) and two identical light (L) chains. Pairing of each H and L chain forms the basic unit of antibody combining sites. In monomeric antibodies such as immunoglobulin G (IgG), IgD, IgE and the majority of the serum IgA, two pairs of H and L chains, linked by disulfide bonds in the hinge region

Figure 1 Schematic view of four-chain structure of human IgG1 molecule. Numbers on right side denote actual residues of protein Eu (Edelman *et al*, 1969). Numbers of Fab fragment on the left side are aligned for maximum homology; light and heavy chains are numbered according to Wu and Kabat (1970) and Kabat and Wu (1971). Heavy chains of Eu have residue 52A and 82A,B,C and lack residues termed 100A,B,C,D,E,F,G,H,I,J,K and 35A,B. Thus, residue 100 (end of variable region) is 114 in actual sequence. Hypervariable or complementarity-determining regions (CDRs) are shown by heavier lines. V_L and V_H denote light- and heavy-chain variable regions; C_{H1} , C_{H2} and C_{H3} are domains of constant region of heavy chain; C_L is constant region of light chain. The hinge region in which two heavy chains are linked by disulfide bonds is indicated approximately. Attachment of carbohydrate is at residue 297. Arrows at residues 107 and 110 denote transition from variable to constant region. Sites of action of papain and pepsin and locations of a number of genetic factors are given. (Reproduced from Kabat EA *et al* (1987).)

of H chains, form two identical antibody combining sites; secretory IgA may be dimers or trimers with four or six binding sites; IgM isotype is pentameric, bearing ten identical sites. For a given Ig isotype, the amino acid sequences in the C-terminal domains are basically identical, termed the constant region (C); those of the N-terminal domains are highly variable, called the variable region (V). Avidities of antibodies are associated with H chain C region isotypes; affinities or binding specificities are determined by V region structures.

Many kinds of substances, when introduced into the body, may induce the formation of antibodies. These include infectious agents such as bacteria and viruses, allo- or xenoantigens of blood cells or other cell types and many substances in the environment or derived from foods, e.g. pollens, shellfish and others to which some people may be allergic. Natural antigens may frequently be complex mixtures of

many antigenic substances. Even highly purified substances such as proteins, polysaccharides, glycolipids or nucleic acids may contain multiple antigenic determinants (epitopes). B lymphocytes comprise an enormous population of distinct antibody-producing cells. Each cell and its descendants synthesize one antibody in response to a single epitope but different cells may recognize different aspects of the same epitope and vary in their binding affinities. Thus, the antibody response of an individual to a bacterium or virus, etc. may involve multiple B cell clones recognizing different antigenic determinants and is said to be polyclonal.

Early studies on specificity carried out on polyclonal populations of antibody yielded much information but the most definitive studies are those using monoclonal antibodies from humans or mice with multiple myeloma or macroglobulinemia and with monoclonal antibodies produced by the hybridoma technique of Köhler and Milstein. Hybridoma antibodies may be produced to any epitope; in practice this may be more difficult, particularly for producing human monoclonals. Cell-cell hybridization for making hybridomas is inefficient and often limited to certain stages of B cell differentiation. Alternative strategies for producing monoclonal antibodies, their Fv, Fab fragments and the engineered single-chain antibodies (scFv), have recently been developed by combining PCR amplification and gene expression. Using advanced flow cytometry, a single B cell, with an Ig receptor of defined specificity as well as other surface markers, may be isolated and its original pair of V_H and V_L chains identified, allowing further exploration of the repertoires of monoclonal antibodies.

Binding specificities of antibodies may be investigated using rationally designed antigens in which one or more chemically defined small substances may serve as antigenic determinants. Thus, diazotized arsanilic acid, dinitrofluorobenzene, etc. may be coupled to a macromolecule to produce an artificial antigen. The antibodies induced will generally react best with, or be most specific for, the group introduced. Thus antibodies to the arsanilic acid-containing macromolecule generally bind arsanilic acid azotyrosine, and those to the dinitrophenyl macromolecule often bind only dinitrophenyllysine. Binding specificities may be further illustrated by competitive inhibition of the reaction by corresponding low molecular weight substances. Competition with structural derivatives differing from the active molecule by defined fine modifications at given positions may allow identification of the critical structures involved in specific recognition. Such low molecular

weight substances are termed haptens; the macromolecules are called carriers.

A potential difficulty in these studies is that the introduced groups are frequently insufficient in size to fill the antibody combining site so that the new epitopes may include a portion of the carrier molecule to which it is linked. Studies with small haptenic determinants, such as phosphorylcholine (PC), 2-phenyloxazolone (phOx), 4-hydroxy-3-nitrophenyl (NP) or dinitrophenyl (DNP) and *p*-azophenylarsonate (Ars) coupled to proteins, may thus not be clearly definable as to what constitutes the antigenic determinant. For example, one may not be able to determine whether sequence differences in the V regions of antibodies induced by these conjugates reflect specificity for different antigenic determinants or are a consequence of specificity differences to a single epitope.

Better understanding of antibody diversity and specificity requires a single site-filling antigenic determinant of well-defined structure. Native dextran N279 is a near-linear macromolecule of glucose linked by 90% $\alpha(1, 6)$ and 5% $\alpha(1, 3)$ glucopyranosidic bonds and has 5% $\alpha(1, 6)$ or other linkages for the glucoses at terminal nonreducing ends. The relative structural simplicity of the carbohydrate antigen, $\alpha(1, 6)$ dextran, provides a model system for such studies. The availability of oligosaccharides of $\alpha(1, 6)$ -linked glucose, ranging from isomaltose (IM2) to [Glc($\alpha(1, 6)$)]₉ (IM9), allow us to 'measure' the sizes of antibody combining sites by competitive inhibition of the dextran-antidextran interaction. The combining site is considered to be complementary in size to the smallest oligosaccharide giving maximum competition. Such an oligosaccharide is defined as an epitope or antigenic determinant. It was estimated by such immunochemical mapping that the antibody combining sites to dextran may vary in size from a lower limit of 1–2 glucoses to an upper limit of 6–7.

To accommodate epitopes with distinct structural properties, different 'shapes' or 'types' of antibody combining sites may be required. For the polysaccharide antigen $\alpha(1, 6)$ dextran, either the nonreducing end sugar or the internal chain structure may function as antigenic determinants. They may be specifically recognized by either cavity- or groove-type combining sites. This was first established by immunochemical mapping of the combining sites of two monoclonal myeloma proteins, W3129 and QUPC52, both specific for $\alpha(1, 6)$ dextran. W3129 had a site saturated by isomaltopentaose, whereas QUPC52 accommodated isomaltohexaose. With W3129, the terminal nonreducing glucose contributed 50–60% of the total binding energy but with QUPC52 less than 5%. The two antibodies also dif-

fered in their ability to precipitate a synthetic linear dextran with about 200 glucoses. QUPC52 but not W3129 forms precipitins in saline. These observations indicate that the combining sites of QUPC52 might be 'grooves' into which internal chain epitopes of $\alpha(1-6)$ -linked glucose could fit; in contrast, the nonreducing ends of dextran may be held by the cavity-type site of W3129. Monoclonal antibodies (mAbs) for 3-fucosyllactosamine, i.e. Le^x, may also accommodate either the nonreducing ends (PM81), or may bind to the side of the sugar chain (PMN6). Crystal structures for these mAbs are currently not available but a few antibodies for other carbohydrate antigens have been crystallized. A $\beta(1,6)$ galactan-specific myeloma protein J539 displays a shallow surface pocket accommodating the polysaccharide antigen; a monoclonal antibody, Se 155-4, binds a trisaccharide of *Salmonella* with the terminal abequose totally buried in a deep pocket of the combining site. Antigen-binding sites, which may be classified as either groove- or cavity-type, are also seen in antibodies specific for other antigens. For example, BV04-01 Fab binds ssDNA with a large, irregular groove and Fab McPC603 has a cavity to accept the hapten phosphorylcholine.

Antibodies may interact with protein antigens with a relatively flat surface. Proteins differ from carbohydrate antigens in their behavior in aqueous solution. Proteins tend to fold to bring their hydrophobic side-chains together, forming an oily core with the polar side-chains exposed. Such folding may allow discontinuous amino acids clustered on the solvent-accessible surface to form discontinuous epitopes. Interior residues are usually not accessible to antibody interactions. A protein epitope may thus be formed either by several contiguous amino acid residues or by discontinuous residues. Of three lysozyme-antilysozyme complexes whose X-ray structures have been determined at high resolution, two antibody combining sites, D1.3 and HyHel-5, each interact with amino acids from two discontinuous stretches of the lysozyme polypeptide chain; the third, HyHel-10, is complementary to the exposed surface of a helix including some surrounding structures. With influenza neuraminidase, four segments of its polypeptide chain were found to interact with the antibody combining site in a resolved crystal structure of their complex. It is thus said that antibodies recognize 'conformation' rather than 'sequence' of a protein epitope.

A discontinuous conformational epitope may be mimicked by molecules having different primary structures. Indeed, antibodies which mimic the structures of other molecules exist. They may be specifically induced by idiotypic-anti-idiotypic interactions.

Antibodies to various antigens may have distinct epitopes in their V regions termed idiotopes, which may be antigenic upon injection. Such induced antibodies are termed anti-idiotypic antibodies. Some anti-idiotypic antibodies may mimic the external antigen that elicited the first antibody reacting with the anti-idiotypic. A complex of antilysozyme D1.3 and its anti-idiotypic E5.2, an internal image type, has been crystallized and its three-dimensional structure clarified. By comparison with the crystal structure of D1.3-lysozyme complex, it was shown that D1.3 contacts lysozyme and the internal image antibody E5.2 through essentially the same combining site residues. In addition, E5.2 interacts with D1.3, making contacts similar to those between lysozyme and D1.3. Functional mimicry of a small biologically active compound, taxol, by an anti-idiotypic antibody 82H has been recently reported. Like taxol, this anti-idiotypic antibody can promote and stabilize microtubule assembly. We must still learn how the three-dimensional structure of 82H can mimic a ligand molecule that bears no structural similarity to immunoglobulins.

There is also evidence that variable regions of antibodies with radically different primary structures may accommodate identical epitopes. A mouse mAb specific for blood group substance A and a human antibody to the same antigenic determinant were found to have very different amino acid sequences in their V_H and V_L domains. Their fine specificities to substance A are indistinguishable by current immunochemical analysis. More examples are seen in anti- $\alpha(1, 6)$ dextrans. mAbs to $\alpha(1, 6)$ dextran may be either groove-type or cavity-type, and sites defined as the same could be very similar immunochemically. Their Ig-V region sequences were determined, showing at least 18 distinct combinations of V region genes and segments of different primary structures, 15 combinations for the groove-type combining sites and three for the cavity-type sites. A definitive answer to the paradox of 'diverse sequence-similar site' will come from X-ray crystallographic analysis of these antibodies and their ligand complexes as well as from a dynamic analysis of their solution conformers applying nuclear magnetic resonance (NMR) and other advanced methods.

To understand better the relationships of structural diversity of antibody combining sites and their complementarity and specificities, the critical structures defining the prototypes or shapes of antibody combining sites and their fine specificities should be identified. Analysis of V region sequences led to recognition of hypervariable or complementarity-determining regions (CDRs) in V domains of antibodies. In the early 1970s, Wu and Kabat examined

about 70 human V_K and V_L and mouse V_K sequences and introduced an equation, termed a variability plot for analysis:

$$\text{Variability} = \frac{\text{Frequency of the most common amino acid at a given position}}{\text{Number of different amino acids at that position}}$$

When variability was plotted against amino acid residue number for the 107 residues in the V region, three peaks of high variability were seen at positions 24–34, 50–56 and 89–97, bracketed by invariant or almost invariant residues with length variations at residues 27A–27F and 95A–95F (Figure 2). As V_H

Figure 2 (A) Variability at different positions for the variable region of light chains. GAP indicates position at which differences in length have been found. sequences of various species become available, three hypervariable regions were also found at positions 31–35, 50–65 and 95–102; with length variations listed as 35A and 35B, 52A to 52C and 100A to 100K (Figure 2B). Considerable three-dimensional information has now become available by X-ray crystallography. All high-resolution X-ray structures verified the prediction and showed that the hypervariable regions, as defined, formed the antibody combining site. These are termed CDRs and the rest of the V_H and V_L domains form a framework (FR). Comparison of the three-dimensional structures of variable domains of different antibodies reveals that the nonhypervariable or framework regions of these domains are essentially superimposable. Structural variations related to antibody specificity are mainly confined to the hypervariable segments. Amino acid residues of antibody in actual contact with antigenic determinants are found predominantly in the CDR regions. The antibody combining site can thus be viewed as being formed by a relatively small number of segments of variable structure grafted on to a scaffolding of essentially invariant architecture. In three dimensions, these variable segments or CDRs are seen as a loop structure situated at the N-terminal tip of an antibody. Their combination forms a continuous solvent accessible surface, the CDR surface, approximately $2800 \text{ \AA}^2$ in area.

In the crystal structure of antibody–ligand complexes, a portion of the CDR surface may be buried by the ligand; likewise, those of the ligand covered by the antibody. Such a buried area is termed a contacting surface, representing the actual sizes and shapes of antibody combining sites. Different types of interaction, such as reacting to protein, to polysaccharide or to small haptens, may differ significantly in the area of their contacting surface as well as the nature of their three-dimensional complementarity. In Fab-Se 155-4 complexed with a branched trisaccharide α -D-Galp(1–2)[α -D-Abep(1–3)]- α -D-Manp of *Salmonella*. The terminal abequose fills the hydrophobic pocket of the antibody, with contacting surfaces of $255 \text{ \AA}^2$ for the buried sugar epitope and $304 \text{ \AA}^2$ for the antibody, corresponding to the lower limit of site sizes estimated by immunochemical mapping of antidextran. For a carbohydrate–lectin complex, the interface of ligand Le^b and its receptor OMe.GS-IV shows complementarity of polyamphiphilic properties of their contacting surface, with buried areas of $237 \text{ \AA}^2$ and $265 \text{ \AA}^2$, respectively. The changes of contacting area of these carbohydrate receptors is similar to that for binding of haptens by antibodies but much smaller than the interfaces of proteins and their antibody combining sites. McPC603 contacts phosphorylcholine by $151 \text{ \AA}^2$

and $138 \text{ \AA}^2$; Fab AN02 and DNP-spin-label by $363 \text{ \AA}^2$ and $230 \text{ \AA}^2$; and Fab 4-4-20 with fluorescein by $338 \text{ \AA}^2$; and $247 \text{ \AA}^2$. Protein antigens may interact with antibody combining sites with a relatively larger surface. In Fab–lysozyme complexes, lysozyme was bound by HyHEL-5 with buried surface areas of $768 \text{ \AA}^2$ and $723 \text{ \AA}^2$, the HyHEL-10 complex of $699 \text{ \AA}^2$ and $753 \text{ \AA}^2$, and the D1.3 complex by $512 \text{ \AA}^2$ and $524 \text{ \AA}^2$. Their binding constants (K_d) are $5 \times 10^{-11} \text{ M}$, $2 \times 10^{-10} \text{ M}$ and 10^{-10} M , respectively. Binding of carbohydrates by antibodies or by lectins is specific but binding constants are often several logs lower than antibody–protein interactions, generally 10^{-3} M to 10^{-6} M . Possible correlations between their limited contacting areas and the low binding affinities may be evaluated when more crystal structures become available.

The topographic properties of the contacting surface are mainly determined by the loop configuration of individual CDRs and their relative disposition. These, in turn, are determined by the number and nature of amino acid residues in CDRs. There are residue positions in CDR which are more conserved than others and were postulated to be structural or conformational elements. On the basis of comparative studies of known crystal structure of antibodies and sequences, Chothia and colleagues found that the loop conformation of CDRs is determined by a few conserved residues in a CDR segment and suggested that there is a small repertoire of main chain conformations for at least five of the six CDRs of antibody, termed canonical structures. The length variation of CDR segments is also important for their loop conformations. Among six CDRs, only the V_L -CDR2 is conserved in length, with seven amino acid residues (Figure 2) in all productive V_L chains so far identified. A unique canonical structure fits 95% of 69 human V_L and of 183 murine V_L analyzed. The V_H -CDR3s vary extensively not only in residue composition but also in the number of their amino acid residues. No canonical structures can be assigned to this region. For the rest of CDRs, distinct canonical structures can always be identified among segments of a given CDR when they differ in length by as little as a single amino acid residue.

To form a given prototype of antibody combining sites, a certain combination of CDR loops may be required. For example, a long V_H -CDR3 and a long V_L -CDR1 are common to the cavity-type combining sites of different specificities, including all the cavity-type anti- $\alpha(1, 6)$ dextran so far sequenced, anti-phosphorylcholine mAb McPC603 and anti-3-fucosyllactosamine PM81. Modeling of these sites showed that this CDR loop combination is required to form the cavity wall of the combining sites. With

the groove-type sites, a short V_L -CDR1 lacking amino acid residues 27 and 28 is predominantly seen in anti-dextran; a few exceptions have either a long V_L -CDR3 or a long V_H -CDR, but not both. Lara-Ochoa and coworkers analyzed the combinations of the canonical CDR structures of murine Ig sequences provided by the on-line server of the KABAT database. Of 519 murine antibodies studied, only 33 combinations of at least 300 total expected combinations are actually found. About 85% of the antibodies fall into only six different combinations of canonical structures. These distinct groups correlate to the types of antigen with which they interact. It was suggested that relatively small numbers of canonical structural combinations of CDR segments may primarily determine the 'prototypes' or 'gross' specificities of the antibody combining sites. Further diversification of these structures are required to generate a wide variety of antigen-binding specificities.

The molecular mechanisms underlying antibody diversity have been extensively studied. The intact V_H or V_L chains are assembled by genetically separated elements, V_H genes, D and J_H segments or V_L genes and J_L segments, by a site-specific recombination event the V(D)J rearrangements. CDR1 and CDR2 are encoded by the V_H or V_L genes; the CDR3 regions are generated by recombination events, V_L -CDR3 joined by V_L and J_L , and the V_H -CDR3 by V_H , D and J_H . N or P element insertions may occur at either V_H -D or D- J_H junctions. D-D fusion may also occur during the V_H -D- J_H recombination but at lower frequency. Sequences and lengths of V_H -CDR3 are therefore the most variable. A rearranged antibody molecule may be further diversified by another somatic molecular process termed 'hypermutation', which may be induced during an immune response to antigenic stimulation, typically those elicited by T-dependent protein antigens. In the nonimmunized repertoire or the 'natural antibody' population, antibodies with low affinity and cross-reactivity are frequently seen. They are usually encoded by germline V region genes without or with few somatic mutations. Antibodies with relatively high affinity may be obtained during secondary immune responses or later but generally not at the stage of the primary response. Point mutations are frequently observed in their V regions. The process by which an antibody with low affinity is further diversified by point mutations to high affinity is termed 'affinity maturation'. This process is believed to occur in the germinal centers of lymphoid tissue and requires help by T lymphocytes and other accessory cells. The molecular mechanisms underlying hypermutation and how it contributes to the affinities and specificities of antibody combining sites are less understood.

Since V(D)J recombination occurs at the pre-B cell stage and secondary rearrangements appear very infrequently, a 'matured' high-affinity antibody may preserve the lengths of its six CDR loops and the canonical structural combination of its parent antibody, i.e. the rearranged unmutated germline antibody, unless mutations occurred at the conserved CDR residue positions which are considered as those critical for the canonical structure of CDRs. Comparison of such matured high-affinity sites and their low-affinity germline antibody may allow us to investigate how somatic mutation contributes to the affinity maturation. Patten and colleagues studied a catalytic antibody 48G7 and its germline partner. They reconstructed and expressed the Fab segments of 48G7 as well as the germline antibody. The active catalytic antibody 48G7 differs from the germline partner by nine replacement mutations, six in CDRs and three in FRs. None of the six CDR residues, two in V_L -CDR1, one in V_L -CDR2 and three in V_H -CDR2, examined using Chothia's definition, can be classified as 'key residues' for the canonical structure of the CDRs. Thus, the two antibodies have the same combination of canonical CDR structure. These mutations, however, resulted in increased affinity for the transition state analog by a factor of 10^4 and also enhanced catalytic activity with the rate K_{cat}/K_m , from $1.7 \times 10^2 \text{ M}^{-1} \text{ min}^{-1}$ to $1.4 \times 10^4 \text{ M}^{-1} \text{ min}^{-1}$. The three-dimensional crystal structure of the 48G7 Fab-hapten complex was resolved to 2.0 Å, allowing the identification of amino acid residues which contact the bound hapten. Surprisingly, none of the nine residues generated by somatic mutation contacted the ligand directly. They are all noncontacting residues. It was suggested that these mutants played roles in fine tuning of the combining site, by optimizing the geometries for hapten binding. These studies emphasized that the relative contribution of the CDR contacting and noncontacting residues and their cooperative interaction to antibody specificity need further investigation.

Since the discovery of antibody more than 100 years ago, much has been learned about this molecule. It has become possible to ask whether an antibody combining site of a given specificity may be designed and synthesized. To realize this long-term goal, additional efforts must be made to understand further the relationship of structural diversity and complementarity, to identify the critical structures which define three-dimensional complementarity in overall shapes or gross specificities, and to define those which may further optimize the fine geometries of antibody combining sites to achieve directed specificities. To facilitate these studies, a combination of advanced approaches, including X-ray crystallogra-

phy, NMR, computer modeling, molecular engineering, immunochemical analysis and other methods for determination of fine specificities should be applied in rational designed experiments.

ANTIBODIES, SYNTHESIS

Fritz Melchers, Basel Institute for Immunology, Basel, Switzerland

The human immune system contains 10^{11} – 10^{12} B lymphocytes, which synthesize the 10^{20} antibody (immunoglobulin, Ig) molecules found inside and on the surface of these cells and, most of all, in the serum. Other mammalian species contain B cells and Ig molecules in numbers relative to their body weight, e.g. mice have 10^9 B cells and 10^{17} Ig mol-

ecules. Both B cells and Ig molecules turn over; both are synthesized and degraded throughout life.

Antibodies are glycoproteins composed of glycosylated heavy (H) chains and (mostly unglycosylated) light (L) chains. The amino-terminal domains of both H and L chains are variable (V) from antibody to antibody; they bind antigen. The other, more car-

boxy-terminal, constant (C) domains are involved in functions of antibodies which are unrelated to their individual antigen-binding specificities, but are carried out by antibodies of a given class or subclass, e.g. complement binding and activation, binding to Fc receptors on surfaces of cells, or transport through cells. Genes encoding H and L chains are encoded by segments which have to be rearranged before the genes can be transcribed and translated. The rearrangements of gene segments occur when B cells develop from B lineage-committed progenitor cells. Therefore, rearranged Ig genes only exist in cells of the B lineage, but in no other cells of the body.

Development of B lineage cells and rearrangements of Ig gene loci

In humans (and mice) three Ig gene loci can be rearranged. The H chains on human chromosome 14 (chromosome 12 in mouse) with the μ -, δ -, γ_{1-4} , α_{1-2} and ϵ C-region genes, κ L chains on human chromosome 2 (chromosome 6 in mouse) and λ L chains on human chromosome 22 (chromosome 16 in mouse). During B cell development (in humans at around 10 weeks, in mice between day 10 and 18 of gestation) B cells are generated in waves. In the mouse a first wave in embryonic blood and placenta is succeeded by a second wave in fetal liver. Throughout life B cells continue to be generated in bone marrow at a rate of 5×10^7 cells per day in the mouse (approximately 10^3 -fold more in humans), of which 0.5–5% become mature, surface Ig (sIg)-positive cells of the periphery. Most newly generated B cells therefore die at the site where they have been generated.

From pluripotent stem cells which are the ancestors of the different lineages of blood cells, progenitors develop which are committed to the B lineage.

A collection of intracellular and surface-bound marker molecules has allowed the separation of subpopulations of B lineage cells from fetal liver and bone marrow, and single-cell PCR analyses of the status of the Ig gene loci have been useful to order these cell populations on their way from a pluripotent stem cell to a mature, antigen-reactive B lymphocyte. Many early cells of B lymphocyte development find themselves, and function, in close contact with an environment of stromal cells which provides specific contacts and cytokines that regulate the proliferation and differentiation of B lineage cells. Interleukin 3 (IL-3) and IL-7 have been identified as such cytokines in the mouse, and c-kit and flk-2 are membrane-bound tyrosine kinases on B lineage precursors

which interact with their corresponding membrane-bound ligands on stromal cells.

The earliest signs of a cell to be committed to the B lineage of development is the transcription of the nonrearranged, germline μ H chain gene locus, the transcription of the V_{preB} and λ_5 genes encoding the surrogate light (SL) chain and the activation of the machinery involved in rearrangements of segments of the Ig gene loci, i.e. the activation of terminal deoxynucleotidyl transferase (TdT) and the recombination activating genes RAG1 and RAG2. This occurs in cells which express B220 (CD45R), but do not yet express CD19, the two markers most commonly used in the characterization of B lineage cells. The first Ig gene rearrangements, D_H segments to J_H segments, are already detectable in these cells. TdT is responsible for N-sequence insertions at the joints of the rearrangements. TdT is active in bone marrow but not in fetal liver. Therefore antibodies derived from bone marrow-generated B cells are N-region diverse (in their H chains); those derived from fetal liver are not.

This ordered rearrangement process continues in the next distinguishable B lineage cell population, which is B220 (CD45)⁺, CD19⁺, also expresses c-kit and SL chain on the surface, and now has practically all H chain alleles D_HJ_H rearranged.

The next rearrangement in-line is V_H to D_HJ_H on one of the two H chain alleles. Whenever this rearrangement occurs in-frame, a μ H chain can be made. The μ H chain combines with SL chain and thus forms a pre-B receptor. This development has several consequences which lead to a new cell population. It induces cells into cycle, hence the pre-B receptor-expressing, so-called pre-B II cells are large. Since nonproductively rearranged cells cannot form a pre-B receptor they do not expand by proliferation. Hence, productively rearranged, μ H chain expressing, pre-B receptor-positive cells outgrow this compartment, i.e. are positively selected. They no longer express c-kit and have completely downregulated the rearrangement machinery, i.e. TdT, RAG1 and RAG2. As a new surface marker, they now express CD25 (TAC), the α chain of the IL-2 receptor. Downregulation of the rearrangement machinery is likely to be part of the mechanisms by which the second H chain allele is inhibited from V_H to D_HJ_H rearrangement. Hence it secures allelic exclusion, i.e. that one B cell makes only one H chain sequence.

Large pre-B II cells proliferate for an estimated 3–5 cell cycles, lose pre-B receptor expression, begin to re-express RAG1 and RAG2, and begin to transcribe the nonrearranged L chain gene loci κ and λ . While doing so they fall into a resting state, become small, and hence are called small pre-B II cells. The

rearrangement-active genes RAG1 and RAG2 but not TdT are active; all cells now contain V_L to J_L -rearranged L chain gene loci, but no N-region insertions can be made. Half of them are productively rearranged, express the L chains in their cytoplasm, but not (yet) on their surface. The other half contain nonrearranged, or out-of-frame rearranged L chain loci. Since the pre-B II cells have an active rearrangement machinery, they can engage in secondary V_L to J_L rearrangements which in some cells might change nonproductive to productive L chain gene loci, and which in other cells might change a productive L chain locus encoding an autoantigen-reactive Ig receptor (termed receptor editing). Secondary L chain gene rearrangements might allow a B cell to express two L chains, whenever the rearrangement process allows both L chain alleles to be used. It has been seen that no more than 1–3% of all peripheral mature B cells express two L chains. Since less than 1% of all B cells have been seen to express two H chains, it remains true that for most B cells the rule ‘one B cell makes one antibody’ is valid. This is the basis for clonal selection in the immune system, in which a given antigen selects from all the lymphocytes those which have a fitting receptor on their surface.

The rearrangement machinery continues to be active in the next cell population in-line, the immature, surface IgM-expressing B cells. This is probably useful in editing autoreactive B cells.

The expression of an autoreactive Ig receptor on immature B cells leads to the arrest of differentiation of this cell. Since the cell remains short lived, it will die at this site of development in the primary lymphoid organ unless it can change its receptor specificity through editing. In this way of arrest of differentiation, the emerging B cell repertoire is purged of all B cells which are autoreactive to antigens present and presented in the bone marrow. A classical case for such an autoantigen is double-stranded DNA, present in large quantities due to extensive cell death at this site of development.

Of the sIgM-expressing immature B cells which do *not* recognize an autoantigen at this point of development, a small proportion (2–3%) are chosen each day to become mature, resting antigen-sensitive, sIgM/sIgD double-expressing B cells which are allowed to migrate to the periphery and become eventually longer lived. Whether sIg is involved in this ‘positive selection’, i.e. whether self antigen or foreign antigens are mandatory to make all immature B cells mature, remains to be seen. However, B lineage cells which are defective in T-independent as well as T-dependent B cell activation through mutations in their *btk* and *CD40* genes are unable

to establish longer-lived peripheral, mature B cell compartments, indicating that such stimulatory pathways are involved in the establishment of the peripheral, mature B cell compartments.

It should be mentioned that other species with an immune system might use different strategies to generate antibody diversity. In chicken, as one example, there is only one functional rearrangement of one V_H to a series of different D_H segments and to one J_H segment, and one V_L to one J_L segment generates a very limited original Ig repertoire which is then altered by gene conversion with many pseudo- V_H and pseudo- V_L gene segments, respectively.

As another example, fish carry partially and fully V(D)J-rearranged genes in many copies; hence they rely much less on rearrangements and more on combinations of different H and L chains for antibody diversity.

Selection of the B cell repertoire by self antigens

Once sIg-positive cells have been generated they are subjected to selection processes by self antigens in their own environment, probably presented by cells in the B cell-generating organs. Self reactive B cells appear to be either deleted or anergized. Whether *positive* selection for self antigens can also occur – maybe in a special B lineage, the $Ly-I^+/CD5^+$ B cells – needs to be elucidated.

Those B cells which have been untouched by these selection processes then enter the mature B cell compartment of virgin cells involved in primary B cell responses. Such cells still turn over rather rapidly, with half-lives of less than 1 week. They can be stimulated by foreign antigens, either with the help of T cells (helper T cell dependent) or without such help (T cell independent). Stimulation results in the activation from a resting, G_0 state and entry into the proliferative cell cycle. One cell cycle lasts 20 hours at 37°C and is controlled by several interactions (see below) of antigen, helper T cells, accessory cells and cytokines. Proliferating B cells also mature to Ig-secreting cells. A single activated B cell can balance between proliferation and maturation to Ig secretion. With every successive cell cycle the contribution to Ig secretion increases, so that finally mature plasma cells develop which no longer divide.

Helper T cell-dependent stimulation of B cells

T cell-dependent antigens are often monomeric protein molecules. Stimulation of B cells by such T cell-dependent antigens begins with the binding of anti-

gen to sIg on fitting B cells. The complex of sIg and antigen is taken up by the cell, processed by proteolytic degradation, and the processed antigen in the form of peptides combines with class II major histocompatibility complex (MHC) molecules, so that the peptides of the antigen appear associated with the MHC class II on the surface of B cells. Upregulation of MHC class II expression might be necessary to mediate effective recognition and interaction of the complex with the T cell receptor of antigen-specific helper T cells, and IL-4 produced by helper T cells (or other cells) has been recognized as one major cytokine involved in the upregulation of MHC class II expression. This interaction might result in cross-linking of MHC class II molecules followed by signaling to B cells to proceed in the cell cycle. The same helper T cells have also seen the processed antigen on accessory cells such as macrophages, again an association with MHC class II molecules. In response to the T cell-induced signaling, these accessory cells may have produced cytokines which now interact with B cells at the entry into S phase. T cell-dependent B cell stimulation is, therefore, dependent on accessory cells. Activated helper T cells contribute to B cell stimulation in various ways. Activation of resting helper T cells by the recognition of the MHC class II-antigen-peptide complex on antigen-presenting accessory cells (dendritic cells, macrophages), leads to the upregulation of expression of the ligand for CD40 and to the upregulation of cytokine expression such as IL-2 (by helper T cells of type 0 and type 1), and of IL-4 and IL-5 (by helper T cells of type 2). In addition, different cell-cell contacts mediated by, for example, CTLA-4 and CD28 on helper T cells with B7-1 and B7-2 on B cells appear to guide the responses of B cells to IgM production (T_H0 and T_H1), or IgG and IgE production (T_H2), and the memory responses of B cells. In summary, T cell-dependent activation controls the B cell cycles at four points: 1) by antigen via sIg; 2) by T cell receptor interaction via processed antigen and MHC class II molecules, both in the G_1 phase; 3) by cytokines from accessory cells and by CD40 ligand from helper T cells at the entry of S phase; and 4) by IL-2 or IL-5 from helper T cells via IL-2 and IL-5 receptors before mitosis, and by additional cell-to-cell contact.

Synthesis of antibody with different H chain classes: the problem of H chain gene switching

T cell-independent antigens stimulate IgM- and IgG-synthesizing and secreting B cell clones, without any strong switching to other classes of IgH chains. T cell-dependent antigens, however, stimulate IgM-

secreting B cell clones and induce the switching to other classes of IgH chains in these clones. Different helper T cells in different lymphoid organs may induce the switching to different classes of H chains. T cells secreting IL-4 induce switching to IgG1 and IgE.

Somatic hypermutation of Ig genes

T cell-dependent stimulation generates memory for the antigen in the immune system. This may be so because T and B cells specific for the antigen are now present in higher numbers, because B cells have a longer life in the system and because B cells with better fitting sIg have been made by hypermutation of Ig V regions. With a hypermutation rate estimated to be as high as 10^{-3} per base pair per division, one nucleotide of a V gene is mutated with every B cell division. Antigen continues to select any better fitting Ig on a mutated B cell in the T cell-dependent fashion of clonal stimulation described above. Much of this appears to occur in germinal centers. T cell-dependent stimulation to germinal center formation, Ig class switching and hypermutations is abolished when CD40 is made nonfunctional in B cells by targeted disruption of the gene.

Mutations of B cells to specificities recognizing self antigens may occur, but these autoimmune B cells are not dangerous as they are not selected for further growth. This is because any processed self antigen on MHC class II is not recognized by the helper T cells which are specific for foreign antigens, and because helper T cells for self antigens are absent from the immune system due to deletion in the thymus during their generation.

T cell-independent B cell stimulation

Two types of T cell-independent antigens (types I and II) stimulate B cells without involving MHC class II molecules, i.e. in a non-MHC-restricted fashion, to proliferation and to maturation into antigen-secreting cells. Memory to these antigens is normally not induced; the responses remain mainly IgM response and little, if any, hypermutation of IgV genes is observed. The stimulated B cells remain short lived. Typical type I antigens are those connected to lipopolysaccharide (LPS), while type II antigens are often polysaccharides.

T cell-independent antigens usually consist of repeating determinants with the capacity to cross-link sIg, probably without ever being taken up and processed by the B cells. Three restriction points control the cell cycle of a B cell activated by a T cell-independent antigen: 1) antigen binds to sIg early in

the G₁ phase; 2) at entry into S phase CR2 receptors are ligated; and 3) at entry into mitosis IL-2 or IL-5 bind to their corresponding receptors. T cell-independent antigens of type I do not need IL-2 or IL-5 to stimulate B cells at the third restriction point. Other cytokines, such as IL-1, IL-4, IL-6 and interferon γ (IFN γ) have positive and negative modulating functions for proliferation and/or maturation of B cells.

Synthesis, intracellular transport, surface deposition and secretion of Ig chains

When the Ig gene segments have been rearranged, the Ig gene loci can be transcribed, and the primary transcripts processed into mature mRNA. Transcription is controlled by B lineage-specific promoters and enhancers, so that 50–100 mRNA molecules for μ H chains, and later for L chains, are found in a pre-B cell. This suffices to maintain the synthesis of approximately 5×10^4 μ H chains of membrane bound type (μ_m), and later the same amount of L chains, in 24 hours. As long as pre-B cells divide, most of the newly synthesized molecules are incorporated into newly generated surface membranes used in cell replication. Some of the 7–8S μ H₂L₂ sIgM-positive B cells shed these molecules rapidly, i.e. with a half-life of 2–4 hours, from the pre-B cells. At early stages of B cell development, before the expression of L chains, these 7–8S sIg molecules contain V_{preB} λ_5 as a surrogate L chain. Later, when B cells fall into the G₀ resting phase, the same amount of Ig μ H and L chain synthesis provides the 7–8S μ H₂L₂ molecules shed from the cells with a slow turnover (half-life of 24 hours). The transmembrane portion of μ H_m determines its deposition in the surface membrane.

Within 2 hours of stimulation, resting B cells change the rate of IgM synthesis by a factor of 5, and within the next 2 days by a factor of 20–100. This is achieved by stabilization of mRNA and an increase in the rate of transcription. The increase in IgM synthesis is devoted entirely to the synthesis of the secretory form of μ H chains (μ_s). Splicing of precursor RNA into mature mRNA is altered from μ_m to μ_s type. Within 4 hours of stimulation, 19S (μ H₂L₂)₅ pentameric IgM is secreted from stimulated B cells. Synthesis of J chain is stimulated, and J chains become associated with 19S IgM. Beyond 2

days of stimulation, the rate of IgM synthesis increases by another fivefold. In these later phases of B cell maturation, plasma blasts enlarge their endoplasmic reticulum (ER) and accumulate intracellular Ig (from 5×10^4 – 5×10^6 molecules per cell).

IgH and L chains are synthesized and transported through the cell by the conventional pathway for secreted proteins. H and L chains are synthesized on separate polyribosomes. It takes 30–40 s to synthesize an L chain, and around 90 s for an H chain. Translation is initiated on free ribosomes. As soon as the amino terminal leader sequences of H and L have been synthesized, they allow the binding of the ribosomes to the rough endoplasmic reticulum (RER) and then, the translocation of the nascent chains through the ER membrane. On the cisternal side, the leader sequence is enzymatically cleaved, and the H chain is glycosylated by the transfer of core oligosaccharides in the form of dolichol-phosphate intermediates to Asn-X-Ser/Thr acceptor sites. The H and L chains are successfully S–S bonded, the carbohydrate portions first trimmed, then terminal sugars added, as the Ig travels from the RER to the smooth ER (SER) and the Golgi apparatus. In mature plasma cells Ig is held intracellularly, particularly in the SER. At the late stage of plasma cell maturation, a single Ig synthesizing and secreting cell contains between 1 and 4×10^6 mRNA molecules for H and L chains, from which it synthesizes and secretes 10^3 – 10^4 Ig molecules per second.

ANTIBODY-ANTIGEN COMPLEXES, THREE-DIMENSIONAL STRUCTURES

The advent of monoclonal antibody technology has made possible structural studies of antibody-antigen complexes by providing large quantities of unique molecular entities. Since the mid-1980s, structural studies of antibody-antigen complexes have encompassed a wide variety of antigens ranging from small molecules through peptides and oligosaccharides to proteins, including several anti-idiotypic-idiotypic complexes (Table 1). All antibody-antigen complexes have shown that the antibody has achieved specificity and affinity through interactions of an antigen-binding site, made up principally, but not exclusively, of residues from the complementarity-determining regions (CDRs), with the antigen. However, the shape of the antigen-binding site and specific interactions have varied considerably depending on the size, shape and surface polarity of the antigen.

Extent and nature of the interface between antibody and antigen

The amount of surface buried in the interaction between antigen and antibody varies with the size of the antigen, from $\sim 1.7 \text{ nm}^2$ to $\sim 9 \text{ nm}^2$ on each surface (Figure 1). The surface area of interaction may also be limited by the size of the antigen-binding site for the largest protein antigen studied (neuraminidase). In the case of protein antigens only a small percentage ($\sim 10\%$ to $\sim 15\%$) of the total antigen surface area is buried in the interaction. Conversely, for most small molecules, the interaction buries 50–90% of the total antigen surface. The surfaces of interaction vary from deep pockets (Figure 1A) to broad shallow pockets (Figure 1B) to grooves (Figure 1C) for small molecules including carbohydrate and peptides. In contrast, antigen-binding sites are relatively flat for protein antigens (Figure 1D). However, in all cases the surfaces are rather complementary with limited space for water molecules in some antibody-protein complexes.

The number of residues involved in the interaction between antibody and antigen also varies with size of the antigen. For smaller antigens, as few as eight residues may be involved on the part of the antibody. For protein antigens, typically 14–21 residues are in contact on both molecules. The antibody-binding

sites on protein antigens (epitopes) consist of 2–5 sequentially discontinuous segments that are spatially contiguous (Figure 1D). Similarly, antigen-binding sites on antibodies (paratopes) consist of 4–6 CDRs that are spatially contiguous (Figure 1A–D).

In the typical complex the heavy chain contributes more surface area and residues to the interaction with antigen, ranging from just over 50% to almost 80%. One exception to this rule is the antibody AN02, where the light chain contributes a majority of the interactions. The CDRs that typically make a preponderance of the interactions are the third CDR of the light chain and the second and third CDRs of the heavy chain. Most complexes with small molecules and some complexes with proteins do not involve the second CDR of the light chain. In contrast, the NC41-neuraminidase complex does not involve the first CDR of the light chain and a few protein complexes have rather minimal involvement of either the third CDR of the light chain or the third CDR of the heavy chain.

Chemical nature of the interactions between antibody and antigen

The interactions of antibody with antigen are generally van der Waals interactions involving surface residues, which despite being solvent exposed are relatively hydrophobic in nature. However, most antibody-antigen interactions contain at least one hydrogen bond or salt link and typically contain many. For example, protein antigens form on the order of 15–20 hydrogen bonds and/or salt links with antibody. However, it is impossible to extrapolate from the number of hydrogen bonds and salt links to the strength of the interaction between antibody and antigen. For example, the 26-10-digoxin complex has no hydrogen bonds and no salt links, but its association constant ($\sim 1 \times 10^{10} \text{ M}^{-1}$) is as strong as any whose three-dimensional structure is known. In the antibody-protein complexes, some water molecules have been found to be part of the interface between antibody and antigen.

In the antigen-binding site, tyrosines and tryptophans occur more frequently than in the rest of the antibody. These two residues are both capable of forming hydrogen bonds to solvent or antigen, but have

^bAntigen names: HPr, histidine-containing protein of the phosphoenolpyruvate:sugar phosphotransferase system; FMDV, foot-and-mouth disease virus; TEMPO-DNP, 2,2,6,6-tetramethyl-1-piperidinyloxy dinitrophenol; EOTUBE, 4-[N'-(2-hydroxyethyl)thioureido]-L-benzyl-EDTA; NC174, N-(p-cyanophenyl)-N'-(diphenylmethyl)-N''-(carboxymethyl)guanidine.

Figure 1 Binding sites and buried surfaces (represented as dots) of selected antibody-antigen complexes demonstrating different sizes and shapes of binding interfaces. For each complex, on the left the antibodies are shown with antigen-binding site face-on and on the right rotated 90° about the horizontal relative to the figure on the left. In both views the light chain is on the left. In the right image, the viewer is looking from CDR-L3 towards CDR-H3, which is in the back. Antibody backbone is represented as a ribbon. To the far left and far right of the antibody structures the small molecule antigens for the first three complexes are represented as ball-and-stick in the orientation that they are bound to the antibody. (A) 26-10-digoxin; (B) BR96-Lewis Y; (C) 50.1-HIV gp120 V3; (D) HyHEL-5-lysozyme. Note the deep pocket of 26-10, the broad pocket of BR96, the groove of 50.1 and the relatively flat and extensive surface of HyHEL-5. (Figure produced with MOLSCRIPT by Per Kraulis.)

large hydrophobic surfaces. Moreover, these large hydrophobic surfaces can be immobilized with limited entropy loss due to restricted rotation of bonds in the complex. Thus the preference for tyrosines and tryptophans is most likely due to the unique nature of the antigen-binding site, which spends part of its time accessible to solvent and part of its time buried in a complex.

Conformational change upon complexation of antibody and antigen

A range of motions have been found for antibody and for antigen upon complexation. From most global to most local these include: rotation of V_H relative to V_L , conformational rearrangement of the polypeptide backbone, rigid-body motion of polypeptide backbone segments, and side-chain motion. Examples of antibody motion have been principally found with antibodies to small molecules including peptides and carbohydrate, but this may be due to

the limited number of structures of uncomplexed antibody available for protein-specific antibodies (Table 1). An example of rotation of V_H relative to V_L and of conformational rearrangement of the third CDR of the heavy chain may be seen in Figure 2A. The effects of these motions on opening the antigen-binding site may be seen by a comparison of Figure 2B with Figure 2C.

Anti-idiotypic complexes

A number of anti-idiotypic complexes have been reported (Table 1). However, the lack of availability of the structure of the original antibody in complex with antigen has limited the ability to describe mimicry of the antigen by the idiotypic antibody. In the case of the D1.3 antibody, whose structures both uncomplexed and in complex with antigen (lysozyme) have been determined, two anti-idiotypic complex structures have also been determined. One (E225) blocks the antigen-binding site, but does not

Figure 2 Comparison of complexed and uncomplexed forms of 50.1 showing the change of the binding pocket between the uncomplexed and complexed forms. (A) Superposition of V_L domains of 50.1, showing changes due to differences between relative position of V_H and conformational differences of the third CDR loop of the heavy chain (complexed antibody in black and uncomplexed antibody in white). (B) Binding site (as represented by a dot surface) of complexed form of 50.1. (C) Binding site (as represented by a dot surface) of uncomplexed form of 50.1. The third CDR of the heavy chain is towards the top center of the figures. (Figure produced with MOLSCRIPT by Per Kraulis.)

mimic the surface of the antigen. In contrast, the other (E5.2) blocks the antigen-binding site and appears to mimic the interactions of lysozyme with D1.3 to a high degree.

Future directions

The future of structural work in the antibody-antigen complex field will probably be driven by four forces: 1) the use of antibody-antigen complexes as model systems for examining protein-protein interactions, which includes the ability of the immune system to find multiple solutions to binding to the same surface (epitope); 2) the study of camelid antibodies, which have single, heavy-chain binding domains rather than the more common $V_L:V_H$ heterodimers (an example of a camel antibody-lysozyme complex has recently been determined (Table 1)); 3) the use of antibodies to crystallize complexes of otherwise refractory proteins, such as human immunodeficiency virus (HIV) reverse transcriptase and cytochrome *c* oxidase (Table 1); and 4) a desire to understand the structural basis of catalytic antibodies of which four examples already exist (Table 1).

ANTIBODY-ANTIGEN INTERMOLECULAR FORCES

Carel J van Oss, Department of Microbiology, School of Medicine, State University of New York at Buffalo, Buffalo, New York, USA

The different types of bonds occurring in the specific interaction between antigen (Ag) and antibody (Ab) molecules are all of the weak physical variety. The three different classes of bonding forces in question are (not necessarily in the order of their relative importance): 1) van der Waals or electrodynamic forces; 2) hydrogen bonding or polar forces; 3) electrostatic forces. Covalent bonds are not involved in Ag-Ab interactions. These physical, noncovalent forces also provide the bonds between other biological entities, such as various ligand and cell surface receptors, carbohydrates and lectins, and enzymes and their substrates. (In enzyme-substrate reactions however, covalent bonds can also occur, in addition to the three types of physical forces mentioned above.)

Human Ab molecules (immunoglobulins) have from two (IgG, IgA, IgD, IgE), to ten identical valencies (IgM), while secretory IgA (S-IgA) has four valencies. Each paratope on an immunoglobulin molecule represents one valency. Ag molecule (or particles) can have from a few to a great many valencies (each epitope represents one valency). The multiple valencies of such Ag molecules may be all different, or all identical, or some epitopes on a given Ag may be different and others the same. Ag and Ab molecules of a given specificity can combine into Ag-Ab complexes in virtually every conceivable proportion: the Ag-Ab reaction is essentially nonstoichiometric. Thus, the valency of an Ag molecule can only be determined under conditions of excess Ag. In both cases the resulting Ag-Ab complexes will tend to be soluble; insoluble complexes only occur at intermediate Ag-Ab ratios, i.e. close to the optimal, or equivalence ratio.

Nature of antigen-antibody intermolecular forces

Van der Waals forces

Also known as electrodynamic interactions, these occur universally between all atoms and molecules, when brought close enough together. Three different but related phenomena contribute to van der Waals interactions: 1) randomly orienting dipole-dipole (orientation) interactions, or van der Waals-Keesom forces; 2) randomly orienting dipole-induced dipole (induction) interactions, or van der Waals-Debye forces; 3) randomly fluctuating dipole-induced dipole (dispersion) interactions, or van der Waals-London forces. Keesom and Debye interactions only occur with molecules which have permanent dipole moments. The van der Waals-London interaction occurs universally and is also present in atom-atom interactions. In condensed media (i.e. in the liquid and the solid phase), on a macroscopic scale (i.e. on a supra-atomic level), it was first shown by Lifshitz that all three varieties of van der Waals forces can be grouped together; they should be treated in the same manner, and the forces decay with distance at the same rate. On a macroscopic scale, which is also the realm of Ag-Ab interactions, the three varieties of van der Waals interactions, grouped together, are alluded to as Lifshitz-van der Waals (LW) interactions. Due to the fact that the total LW interaction between Ag and Ab, in water, not only must account for the interaction between Ag and Ab, but also for the LW interactions between the Ags and the water molecules, and between the water molecules among one another, the *net* LW attraction between such biopolymers is rather strongly attenuated when occurring in water. The net free energy of LW interaction of the Ag-Ab system in water is of the order of: $\Delta G^{LW} = -0.5$ to -5 mJ m^{-2} . For the interaction between one epitope and its corresponding paratope, given an average surface area of the interaction between epitope and paratope: $A = 3 \text{ nm}^2$, the LW

contribution to such an Ag-Ab interaction then corresponds to $\Delta G^{LW} = -0.2$ to -2 kcal mol⁻¹. Thus LW interactions typically represent only between 2 and 20% of the total interaction energy of average Ag-Ab reaction (which is of the order of: $\Delta G^{TOT} = -10$ kcal mol⁻¹).

Hydrogen bonding, or polar forces

These are nonelectrostatic polar (Lewis) acid-base (AB) interactions, which are of considerable importance in strongly polar media such as water. In water, these polar interactions are principally of the hydrogen-bonding variety; their net outcome can be attractive (hydrophobic attraction) or repulsive (hydration repulsion), depending on the circumstances. In either case, net AB interactions are long-range, i.e. they act at a distance of up to about 10 nm. Analogous to LW or apolar interactions, taking place between two different moieties immersed in a liquid, AB interactions taking place in water are the net outcome of the polar interactions between Ag and Ab, and those between Ag and water molecules, as well as those between Ab and water molecules, and between the molecules among one another.

Hydrophilic AB interactions (also known as hydration forces) are the major cause of the net long-range macroscopic scale repulsion between cells and/or biopolymers. This is the principal repulsion force which epitopes and paratopes have to overcome before engaging in the specific microscopic scale attraction that culminates in the Ag-Ab bond.

The equally long-range hydrophobic AB interactions usually represent the principal microscopic scale attractive force between epitope and paratope. Contrary to a still fairly widely held belief, hydrophobic interactions in water need not exclusively take place between two hydrophobic sites. Hydrophobic attractions between, for example, a hydrophilic epitope and a hydrophobic paratope are quite common among Ag-Ab interactions *in vitro* and *in vivo*. As all immunodominant epitopes tend to be hydrophilic, the corresponding paratopic sites usually are hydrophobic. Such hydrophobic paratopic sites are necessarily located in cavities or clefts, thus obviating undesirable aspecific interactions between unduly exposed hydrophobic loci. The driving force for the hydrophobic attraction is the cohesive hydrogen-bonding interaction between the surrounding water molecules. Hydrophobic Ag-Ab interactions, at closest approach, range from -3 to -25 kcal mol⁻¹ and as such usually play the dominant role in the total Ag-Ab interaction.

In contrast to hydrophobic interactions, direct hydrogen bonds are extremely short range in nature, i.e. direct hydrogen bonds only act at a distance of

about 0.1–0.3 nm. Direct hydrogen bond energies range from -1.3 to -3.4 kcal mol⁻¹.

Electrostatic interactions

Electrostatic interactions between Ag and Ab are caused by the attraction between one or more ionized sites on the epitope and one or more oppositely charged sites on the paratope. These charged sites typically are the COO⁻ and the NH₃⁺ groups on ionized amino acids of the Ag (in such cases usually a protein or a peptide) and of the Ab. Of the three classes of forces involved, the electrostatic (or Coulombic) interaction forces are the most influenced by the pH and by the ionic strength of the liquid medium. The pH is important, as it largely determines the degree of dissociation of the COO⁻ or the NH₃⁺ ions. The ionic strength is important, as it governs the value of the electrokinetic, or zeta-potential of the charged sites, as well as of the (Debye) thickness of the diffuse ionic double layer surrounding these sites. At the physiologic ionic strength of 0.15, electrostatic interactions have a maximum range of about 8 nm; at lower salt concentrations the range can be much longer. The free energy of attraction between one COO⁻ and an NH₃⁺ group, at a distance of about 0.3 nm, at physiological ionic strength, is about -7 kcal mol⁻¹; at a distance of 0.5 nm, the electrostatic (EL) energy of attraction is about -5.5 kcal mol⁻¹.

Whilst electrostatic Ag-Ab interactions occur principally between oppositely charged sites on the epitope and paratope, rare instances have been reported of interactions between two negatively charged sites, by the intermediary of Ca²⁺ ions. Ag-Ab systems involved in Ca²⁺ bridging are, for example, polyglutamic acid Ags, recombinant proteins and (occasionally) DNA-anti-DNA complexes.

The obligatory long-range attraction between epitope and paratope

Normally all biopolymers and cells dissolved or dispersed in aqueous media under physiological conditions repel one another, which prevents them from approaching each other more closely than about 3–5 nm. This makes it necessary for specifically interacting epitopic and paratopic sites to be able to attract each other from a distance. Three factors can contribute to make this possible: 1) The specifically interacting sites are small (surface areas usually between 1 and 10 nm²) and the epitope tends to lie on a prominent edge or peak with a small radius of curvature, which enables it to pierce the general repulsion field and to bring it within less than 3 nm of the paratope. 2) The two sites have a significant

electric charge of opposite signs. 3) At least one of the two (usually the paratope) is fairly hydrophobic.

The rate of decay of Ag-Ab interactions with distance

The rate of decay as a function of distance, d , varies considerably in the three different classes of physical bonds. LW interaction energies in the range of virtual contact, up to $d = 10$ nm, varies at $1/d^2$, in a configuration of two flat parallel slabs. Both polar (AB) and electrostatic (EL) energies decay exponentially with distance, d . AB energies decay as $\exp(-d/\lambda)$, where λ is the decay length of water; λ (water) has a value of about 1.0 nm. EL energies decay as $\exp(-\kappa d)$, where $1/\kappa$ is the thickness of the diffuse electrical double layer; at the physiological ionic strength of 0.15, $1/\kappa = 0.8$ nm. As such exponentially decaying forces usually are measurable at distances that are up to ten times longer than the decay length, thus epitope-paratope interactions begin to make themselves felt at a distance, d of about 8–10 nm. Beyond that distance, the generally prevailing AB and EL repulsion acts between Ag and Ab, as it does between most biopolymers and cells, dissolved or immersed in water. At very short distances between Ag and Ab (i.e. $d_0 = 0.16$ nm), the pronounced increase in strength in all three modes of physical bonding, explains why the best 'fit' between epitope and paratope correlates so strongly with the highest binding affinity.

Hybrid intermolecular Ag-Ab forces

Combinations of LW, AB and EL forces all contributing to the Ag-Ab bond in a variety of proportions are more the rule than the exception. In aqueous media, systems interacting exclusively through Lifshitz-van der Waals forces do not occur; such systems only are possible in apolar media such as alkanes, in which all immunoglobulins and most antigens would be insoluble. Exclusively interfacial interactions, i.e. those involving only LW and AB forces, do occur, for example with (electro-) neutral carbohydrates such as dextran as Ags, or with haptens such as 3-azo-pyridine, *p*-azo-toluidine, dinitrophenol, etc. Exclusively electrostatic Ag-Ab interactions also occur, e.g. in the case of dsDNA-anti-DNA. Otherwise, most Ag-Ab interactions involve LW + AB + EL forces in the primary binding interaction between epitope and specific paratope. Thus, in general, $\Delta G^{\text{TOT}} = \Delta G^{\text{LW}} + \Delta G^{\text{AB}} + \Delta G^{\text{EL}}$.

Primary and secondary Ag-Ab bonds

Once the repulsion front is pierced and epitope and paratope have made contact, the epitope-paratope

bond strengthens, either through the sheer effect of the small distance between the two, or because of a qualitative change in the nature of the bond; for example, through expulsion of water of hydration, or (relatively rarely) through formation of direct hydrogen bonds. Also, once epitope and paratope have approached each other closely, in many cases secondary bonds can ensue between biopolymer moieties that are in close proximity to epitope and paratope. Secondary Ag-Ab bonds occur in all cases where the energy of association is smaller than the energy required for dissociation, once the bond has been formed. Secondary bonds tend to be of the interfacial (or LW + AB, or hydrophobic) variety and hardly ever of an EL nature. If one defines ΔG^{TOT} as $\Delta G_{\text{primary}} + \Delta G_{\text{secondary}}$, and $\Delta G_{\text{primary}}$ as the free energy one needs to furnish to prevent the Ag-Ab complex from forming ($\Delta G_{\text{primary}} = \Delta G_{\text{prevention of association}}$), while ΔG^{TOT} equals the energy needed to dissociate the complex, then:

$$\Delta G_{\text{secondary}} = \Delta G_{\text{dissociation}} - \Delta G_{\text{prevention of association}} \quad (1)$$

As one can measure both the energy needed to prevent association, and the energy of dissociation (i.e. ΔG^{TOT}), $\Delta G_{\text{primary}}$ as well as $\Delta G_{\text{secondary}}$ can be determined. Consolidation of intraepitope-paratope binding (e.g. through direct H-bonding or direct EL interactions) also involves $\Delta G_{\text{secondary}}$. The bovine serum albumin (BSA) system: BSA-anti-BSA, is an example of a primary EL bond, and a secondary hydrophobic (LW + AB) bond.

Dehydration of the epitope-paratope interstitial space (which gives rise to the increase in entropy typically observed in Ag-Ab interactions) is another important aspect of the secondary part of the Ag-Ab interaction. Due to that dehydration, the distance between epitope and paratope decreases, which strengthens their attraction. Upon the disappearance of interstitial water, the epitope-water-paratope interaction becomes, at least in part, a direct epitope-paratope attraction that mainly involves high-energy direct LW forces.

Thermodynamics of antigen-antibody interactions

Law of mass action

Writing the antigen-antibody reaction as:

according to the law of mass action the equilibrium

association constant is expressed as (simplified for the case of monovalent haptens, or single epitopes, and monovalent, or Fab-type paratopes):

$$K_a = K_a/k_d = (\text{Ag} \cdot \text{Ab})/[(\text{Ag}) \times (\text{Ab})] \quad (3)$$

where (Ag) is the molar concentration of free Ag sites, (Ab) the molar concentration of free Ab and (Ag·Ab) the molar concentration of the Ag·Ab complex. k_a is the association kinetic constant; it tends to be rather uniform in value and fairly high (10^3 – $10^8 \text{ M}^{-1} \text{ s}^{-1}$); k_d is the dissociation kinetic constant; it varies considerably from case to case (10^4 – 10^6 s^{-1}). To determine K_a as well as the antibody valency (n), one can use either a Scatchard or a Langmuir plot. In the Scatchard approach one plots (Ag-bound)/(Ag) $\times$ (Ab) on the ordinate versus (Ag-bound)/(Ab). The slope then yields $-n \times K_a$ and the intercept with the abscissa, n . With the Langmuir approach one plots (Ab)/(Ab-bound) on the ordinate versus 1/(Ab-bound). Here the slope yields $(1/n) \times K_a$ and the intercept with the ordinate, $1/n$. If the line obtained in a Langmuir plot is not a straight line, the (Sips) heterogeneity index α , may be obtained by determining α such that the plot of (Ab)/(Ag-bound) versus $1/(\text{Ag-bound})^\alpha$, forms a straight line. K_a values usually vary between 10^4 and $10^{11} \text{ l mol}^{-1}$. For plurivalent antigens (i.e. for most antigens), eqn (2) and concomitantly, eqn (3) become more complex. In addition, it should be kept in mind that each of the valencies of a typical protein antigen usually represents a different epitope. A polyclonal antiserum to such a protein antigen then comprises a whole collection of antibodies with different specificities, as well as with widely differing affinities. Thus, for the interaction of such a polyclonal collection of antibodies with a protein Ag, a large series of eqns (2) should be used for which, however, most of the parameters are unknown and probably unknowable. One therefore usually reverts to eqn (3) in its simple form, and tests for heterogeneity in the manner indicated above.

Energetics

For purposes of energetics, the equilibrium binding constant, K_a (see eqns (4) and (5), below) has to be expressed as a dimensionless number (K'_a), in terms of inverse mole fractions. For instance in water, which comprises $55.56 \text{ mol H}_2\text{O l}^{-1}$, a concentration of $1 \text{ mol l}^{-1} = 1/55.56 = 0.018$ mole fraction. Thus, starting with the unit in which K_a is habitually expressed (i.e. in l mol^{-1}) it should be noted that 1 l mol^{-1} becomes $55.56 (\text{mol fraction})^{-1}$. Conversely, to find K_a (in l mol^{-1}) from K'_a , one has to multiply K'_a by 0.018.

From the dimensionless equilibrium association constant, K'_a , the free energy of the Ag–Ab bond can be obtained via:

$$\Delta G^{\text{TOT}} = -RT \ln K'_a \quad (4)$$

where ΔG is expressed in kcal mol^{-1} , R is the gas constant $= 1.986 \times 10^{-3} \text{ kcal K}^{-1} \text{ mol}^{-1}$ and T is the absolute temperature in degrees Kelvin. To obtain ΔG in joules, $R = 8.3144 \text{ J K}^{-1} \text{ mol}^{-1}$. To obtain ΔG in SI units per epitope–paratope bond, one divides R by Avogadro's number N ($N = 6.022 \times 10^{23}$), to obtain Boltzmann's constant k , where k replaces R in eqn (4). To obtain both the enthalpy (ΔH) and entropy (ΔS) components of the binding energy, $\Delta G = \Delta H - T \Delta S$, K'_a must be measured at a number of different temperatures, in which case one can use, as an approximation:

$$(d \ln K'_a)/dT = \Delta H/RT^2 \quad (5)$$

where R again may be replaced by k when working on the molecular scale of single bonds. Once ΔH is known, one obtains $T \Delta S$ from $T \Delta S = \Delta H - \Delta G$. ΔH can also be obtained by microcalorimetric measurements of Ag–Ab reactions.

Contrary to a rather widely held belief, hydrophobic interaction energies are not necessarily mainly entropic: they can be enthalpic, or entropic, or a combination of these in any proportion. With an increase in temperature the total interaction energy tends to change from predominantly enthalpic to mainly entropic (see following section).

Temperature effects

As the reaction usually is exothermic, at room temperature or lower, ΔH is mostly negative, but it can vary from $+10$ to $-20 \text{ kcal mol}^{-1}$. The entropy contribution can vary widely, from -40 to $+80$ entropy units per mole. In Ag–Ab interactions a positive entropy is usually taken to be due to the randomization of previously organized (oriented) water molecules of hydration which, upon closer approach between epitope and paratope, are squeezed out and become part of the bulk liquid.

In many Ag–Ab reactions, an increase in temperature causes ΔH to become less negative. However, this effect tends to be compensated by a concomitant increase in $T \Delta S$, thus leaving ΔG practically unchanged over a fairly wide range of temperatures. The increase in $T \Delta S$ with an increase in T is a consequence of the following phenomenon: At increased T , the molecular hydration energy decreases, which favors the escape of interstitial water of hydration

into the bulk liquid and thus causes an increase in the entropy of the system caused by the randomization of formerly more organized water of hydration. This loss of interstitial water of hydration also causes a decrease in the distance between the epitopic and paratopic sites, which increases their mutual energy of attraction and ultimately becomes, at least in part, a higher energy direct LW bond.

Measurement of Ag-Ab interaction energies

There is a large variety of equilibrium methods by which the parameters on the right-hand side of eqn (4) can be determined, allowing the calculation of K_a and from this value, of K'_a and of ΔG . Among these methods are equilibrium dialysis or ultrafiltration, precipitation methods, analytical ultracentrifugation, gel filtration or size exclusion chromatography, affinity chromatography, fluorescence, fluorescence quenching, fluorescence polarization, immunoassay methods, hapten inhibition methods, nuclear magnetic resonance, electron spin resonance, etc. The powerful new bioaffinity sensor methods should be specially mentioned.

Bioaffinity sensors

The bioaffinity sensor methodology has, since the early 1990s, developed into one of the most powerful approaches to determining the kinetic association (k_a) and dissociation (k_d) constants, and from these the equilibrium binding constant, K_a (see eqn (3), above), and its inverse, the equilibrium dissociation constant, $K_d = k_d/k_a$. By optical means, the thickening of a layer of, for example, Ab, which is continuously deposited by means of a thin stream of an Ab solution moving across a thin layer of Ag molecules, can be monitored in real time. The graph of Ab thickness versus time thus obtained yields the kinetic association constant, k_a . Upon subsequent replacement of the Ab solution with a buffer solution, the kinetic dissociation constant, k_d , is obtained. From these the equilibrium binding constant, K_a , is derived (see eqn (3)).

Concentration dependence of K_a

With polyclonal Abs, for example, in the BSA-anti-BSA system (BSA = bovine serum albumin), 100-fold dilution (at Ag/Ab equivalence) causes an almost 40 000 fold increase in K_a , i.e. from 1.7×10^7 to

$6.3 \times 10^{11} \text{ l mol}^{-1}$. Even with monoclonal Abs a significant increase in K_a with dilution must be expected because greater dilution minimizes steric hindrance. Thus, if one aims to characterize an Ag-Ab system by measuring the K_a value, it is advisable to operate at the lowest practical reagent concentration. For instance in a Biosensor setting, with a constant Ag concentration in the immobilized phase, a 100-fold decrease in the mobile phase (monoclonal Ab solution) typically gives rise to a 70- to 100-fold decrease in k_a and K_a . In general, under similar circumstances, only the lowest feasible Ab concentration in the mobile phase will yield accurate k_a and K_a values.

ANTIBODY-DEPENDENT CELLULAR CYTOTOXICITY

Jorge Raúl Geffner, Instituto de Investigaciones Hematológicas,
Academia Nacional de Medicina, Buenos Aires, Argentina

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

It was first shown by Moller in 1965 that a wide variety of target cells, coated with low amounts of specific immunoglobulin G (IgG) antibodies, can be lysed *in vitro* by lymphocytes not previously sensitized to target cell antigens. Further studies established that nonlymphoid cells such as polymorphonuclear leukocytes, monocytes and macrophages can also mediate this cytotoxic mechanism, known as antibody-dependent cellular (or cell-mediated) cytotoxicity (ADCC). The ability of a given effector cell population to perform this response, however, appears to be strongly dependent on several factors. They include the nature of the target cells, the isotype and density of antibodies coating the target cell surface, the class of receptor for the Fc portion of immunoglobulin molecule (FcR) involved, and the activation state of effector cells. In all cases, ADCC is induced without major histocompatibility complex (MHC) restriction and therefore it is operative in syngeneic, allogeneic and xenogeneic systems.

It should be noted that the specificity of ADCC is conferred by antibodies, which at extremely low concentrations, far below those required for complement-mediated lysis, are able to induce cytotoxicity. In fact, target cells coated with as few as 100–500 immunoglobulin molecules can be destroyed through ADCC.

Although the mechanisms involved in ADCC are still not completely understood, it is well established that ADCC is triggered by the interaction of target cell-bound IgG antibodies with the receptors for the Fc fragment of IgG (FcγR) expressed on the effector cells. These receptors, which act as signal-transducing molecules, are all members of the immunoglobulin-like superfamily of membrane receptors. They are expressed by human hematopoietic cells, including natural killer (NK), B and T lymphocytes, as well as by monocytes, macrophages, polymorphonuclear leukocytes, mast cells and platelets. Most of them express multiple types of FcγR, which fall into three main classes based on structural analysis of the genes and proteins for these receptors: the high affinity FcγRI (CD64), the low affinity FcγRII (CD32) and the low/intermediate affinity FcγRIII (CD16), which involve at least 12 different isoforms.

FcγR mediate a wide array of responses. They range from effector functions, such as ADCC, phago-

cytosis, pinocytosis and release of inflammatory mediators, to immunoregulatory signals, such as modulating antigen presentation, lymphocyte proliferation and antibody production. Triggering of biological responses through FcγR normally requires cross-linking of these receptors, which is usually induced by IgG immune complexes.

ADCC has been defined and characterized in several experimental models performed *in vitro*. Although its relevance *in vivo* has not been clearly established, several lines of evidence suggest that it plays an important role in host immune defense.

Nature of effector cells and antibodies involved in ADCC

NK cells are a subset of lymphocytes, morphologically identified as large granular lymphocytes, which lack typical T and B cell markers and usually express CD16 (FcγRIII) and CD56. They are able to destroy a variety of cell types, in the absence of prior stimulation, through a mechanism known as natural killer cytotoxicity. This cytotoxic response is not restricted by MHC gene products and is induced without antibody participation. NK cells, which comprise about 5% of human peripheral blood lymphocytes, also account for most lymphocyte ADCC activity. Thus, the same lymphocyte subpopulation seems to be capable of mediating distinct cytotoxic mechanisms, i.e. NK cytotoxicity and ADCC, through the activation of different recognition systems.

The ability of NK cells to perform ADCC has been demonstrated employing a wide variety of IgG-coated target cells such as normal, tumor and virus-infected cells, as well as bacteria, fungi and parasites. It is worth noting that in several human infectious diseases the presence of high levels of specific serum antibodies capable of inducing NK-mediated ADCC against the infectious agent has been described. Similarly, high concentrations of serum antibodies, competent to induce ADCC against tumor and allogeneic cells, have also been found in cancer and kidney transplant patients, respectively. These observations suggest that ADCC mediated by NK cells may play an important role in controlling some infection diseases, in antitumor immunity and, probably, in organ transplant rejection.

Although it is well established that NK cells constitute the major lymphocyte subpopulation capable of performing ADCC, the relative contribution of T and B lymphocytes, as effector cells, should be considered. Studies performed with resting T cells have shown that, with few exceptions, they are unable to mediate ADCC. However, since some T cell subsets express Fc γ R only during a narrow window following cellular activation, the possibility that activated T cells mediate ADCC cannot be ruled out. Regarding B lymphocytes, despite the fact that most of them bear Fc γ RII, they are unable to perform ADCC, suggesting that in B cells these receptors do not act as ADCC-triggering molecules.

Phagocytes can mediate the destruction of antibody-coated target cells by two major pathways: either by intracellular killing of target cells following phagocytosis or by ADCC-mediated extracellular lysis of targets. ADCC performed by mononuclear phagocytes has been largely studied employing peripheral blood monocytes, tissue macrophages and monocyte/macrophage-like cell lines as effector cells. Polymorphonuclear-mediated ADCC has been analyzed using peripheral blood neutrophils and neutrophils collected from inflammatory sites. There is general agreement that mononuclear phagocytes and neutrophils are able to mediate ADCC against a wide variety of target cells. In most of the models described, ADCC involves the participation of IgG antibodies, all IgG subclasses being able to mediate cytotoxicity. In contrast, IgM antibodies seem to play no role in the induction of ADCC. IgA antibodies are also unable to induce cytotoxicity, but they are capable of synergizing with IgG in mediating ADCC.

The relevance of ADCC performed by phagocytic cells in defense against disease is still not completely defined. Several lines of evidence strongly suggest that it plays a major role in host acquired immunity against a wide variety of infectious agents. A possible participation of macrophage-mediated ADCC in antitumor immunity has also been proposed. This possibility was recently supported by several studies which demonstrated that the therapeutic efficacy of some monoclonal antibodies, directed against tumor cell-associated antigens, strongly depends on the number of tumor-infiltrating macrophages.

For a long time it was thought that cellular interactions of IgE molecules were restricted to basophils and mast cells, which express a high-affinity receptor for the Fc fragment of IgE (Fc ϵ RI). The discovery of receptors of low-affinity for IgE (Fc ϵ RII; CD23) on mononuclear phagocytes, eosinophils, B cells and platelets suggested that these cellular populations may also be able to respond to IgE. Thus, Capron

and Dessaint showed that macrophage-mediated ADCC induced by specific IgE antibodies against *Schistosoma mansoni* schistosomula led to the death of the parasite. More recent findings have indicated that not only macrophages but also eosinophils and platelets are able to perform IgE-dependent ADCC against helminths. While several lines of evidence strongly suggest that ADCC induced by IgE antibodies plays a major role in resistance to schistosomiasis, its relevance in host immunity against other parasites remains to be established.

Mechanisms involved in ADCC

The mechanisms involved in ADCC are still not well defined. As mentioned above, the cytotoxic response is triggered by the cross-linking of FcR expressed by the effector cells, which is induced by antibodies that coat target cells. It is also well established that cytotoxicity does not involve the participation of a diffusible cytotoxic factor. In fact, when mixtures of antibody-coated and uncoated target cells are incubated together with effector cells, lysis of non-sensitized targets is not observed.

Different metabolic requirements are involved in the induction of ADCC, depending not only on the nature of the effector cells but also on their activation state, the properties of antibodies and the nature of target cells. The role of Ca²⁺ in the induction of ADCC appears to differ for distinct effector cells. It is well known that the stimulation of human neutrophils and monocytes with immune complexes triggers Ca²⁺ mobilization. The increase in [Ca²⁺]_i appears to play an important role in neutrophil-mediated ADCC; however, it represents a secondary phenomenon in monocyte-mediated ADCC. Studies performed to evaluate the role of the cytoskeleton have also demonstrated major differences between neutrophils and monocytes. Thus, integrity of microfilament and microtubule systems is required for neutrophil-mediated ADCC, but it plays no role in cytotoxicity performed by monocytes.

The cytolytic mechanisms responsible for target cell destruction also seem to be quite different in distinct ADCC models. The generation of reactive oxygen intermediates (ROI), such as superoxide anion and hydrogen peroxide, plays a major role in some models of phagocytic cell-mediated ADCC. By contrast, ROI are not involved in cytotoxicity performed by lymphoid cells, which appears to be dependent on nonoxidative mechanisms, including the release of cytoplasmic granules containing perforin and granzymes. Furthermore, employing monocytes from chronic granulomatous disease patients, which generate very limited amounts of ROI, it was found that

oxidative mechanisms play an important role in ADCC mediated by monocytes against red blood cells but not against lymphoblastoid cells. Interestingly, these data indicate that a single type of effector cell is able to perform ADCC towards different target cells via distinct cytolytic mechanisms.

It is possible that many of the variables observed in different models of ADCC may result from the participation of distinct types of FcγR in the induction of cytotoxicity. In this regard, it is noteworthy that FcγR share structurally related ligand-binding domains, but differ in their transmembrane and intracellular domains which mediate intracellular signaling.

Modulation of cytotoxic activity of effector cells

ADCC can be modulated by several cytokines and inflammatory products. Interferon γ (IFNγ) is one of the most important agents capable of increasing ADCC mediated by both polymorphonuclear leukocytes and mononuclear phagocytes. It causes a 5–15-fold increase in the number of FcγRI on monocytes, macrophages and neutrophils, and, moreover, significantly enhances effector cell oxidative metabolism. Both mechanisms seem to be responsible for the increase in ADCC observed after treatment with IFNγ. While interleukin-10 (IL-10) is also able to stimulate FcγRI expression and ADCC in mononuclear phagocytes, both IL-4 and IL-13 downregulate the expression of all three FcγR and strongly inhibit ADCC mediated by either untreated, IL-10- or IFNγ-treated monocytes. Tumor necrosis factor α (TNFα) can also activate ADCC mediated by neutrophils and eosinophils towards tumor cells and schistosomes, respectively. Interestingly, IL-5 has been shown to enhance antibody-dependent lysis of tumor cells mediated by eosinophils but not by neutrophils.

Colony stimulating factors are also powerful stimulators of ADCC mediated by phagocytic cells. Granulocyte-CSF (G-CSF) has been used in clinical studies for the improvement of circulating neutrophil counts. During G-CSF therapy it was observed that the expression of FcγRI is induced on circulating neutrophils. This effect, which results from G-CSF action on myeloid precursor cells, enables neutrophils to mediate high levels of ADCC against tumor cells. Monocyte-mediated ADCC, on the other hand, can be increased by treatment with macrophage-CSF (M-CSF). Measured on a cell-for-cell basis, treated monocytes are 10–100-fold more efficient than untreated monocytes. The ability of granulocyte-macrophage CSF (GM-CSF) to increase ADCC has

also been established. GM-CSF treatment enables eosinophils, neutrophils or monocytes to display high levels of ADCC against antibody-coated tumor cells and significantly increases antibody-dependent killing of parasites by eosinophils.

Other factors are also able to modulate ADCC. The C5a split product of complement activation increases both the expression of FcγRI on phagocytic cells and ADCC. Phagocytic cell-mediated ADCC can also be significantly increased by opioid peptides, such as met-enkephalin. By contrast, glucocorticoids and several compounds able to increase intracellular levels of cAMP, strongly inhibit ADCC.

Even though *in vitro* studies have provided some information about the characteristics of ADCC, much more remains to be learned. As our understanding of the mechanisms involved in the regulation of ADCC increases, this knowledge should be applied to improve the therapeutic efficacy of monoclonal antibodies, not only in cancer immunotherapy but also in the treatment of some infectious diseases, which depends on the recruitment of host effector systems including ADCC.

ANTIGEN-BINDING SITE

Bradford C Braden and **Roberto J Poljak**, Center for Advanced Research in Technology, Rockville, Maryland, USA

Different estimates indicate that the immune system of higher vertebrates can produce antibodies capable of reacting with more than 10^8 different external antigens. Given this physiological diversity of antibody molecules, the molecular structure of their antigen-combining sites has been the object of much speculation and research. Amino acid sequences of immunoglobulin light (L) and heavy (H) chains from human and mouse myeloma proteins indicated the presence of hypervariable regions, located around sequence positions 30, 50 and 100 in each chain. These hypervariable sequences constitute the antigen-combining sites of antibodies and thus are termed complementarity determining regions (CDRs). Because of their sequence hypervariability, the CDRs must possess great conformational diversity, reflecting the potential of antibodies to respond to many different external antigens. Antibody diversity is generated at the genetic level by multiple V_H and V_L genes and segments (D and J), by a somatic recombination process and an antigen-driven somatic mutation mechanism.

The determination of the three-dimensional structure of Fab fragments of myeloma immunoglobulins by X-ray crystallographic techniques indicated that the folding of the polypeptide chain brings the CDRs into close proximity at an end of the antibody molecule. The β -barrel structures of the V domains provide a nearly constant, conformationally stable framework on which different external polypeptide loops, the CDRs, can be placed without adversely affecting the stability of the folding. Their variable lengths, in particular those of the V_L CDR1 and V_H CDR3, have a profound effect on the stereochemistry of the combining site. In addition, part of the interactions between V_H and V_L mediated by the CDRs are important in shaping antigen-combining sites and in determining the preferential pairing of H and L chains.

Molecular structures of Fabs and Fab-hapten complexes

The determination of the first three-dimensional structures of Fab complexes with the haptens phosphorylcholine and vitamin K_1OH , confirmed that the CDRs of both V_H and V_L participate in binding. The contacts of the ligands with the combining site included salt bridges, hydrogen bonds and van der Waals interactions. No conformational changes in the combining site or in other regions of the antibody could be seen by comparing free with liganded Fabs. Thus, an allosteric mechanism by which conformational signals would be transmitted from the combining site to the Fc region was not supported by these structure determinations. Such mechanisms were postulated as a way of activating secondary (effector) functions of antibodies. However, since haptens represent only a fraction of the antigenic determinants recognized by antibodies, the complete antigen-binding site could not be defined by that approach. Moreover, it was thought possible that conformational changes would be observed only if a complex with a macromolecular antigen, contacting a wider area at the combining site, could be studied.

Antibody-antigen complexes

The introduction of cell hybridization techniques leading to the development of immortalized lymphocytic cell lines (hybridomas) secreting antibodies of predefined specificity allowed the production of monoclonal antibodies (mAbs) in large quantities. These made it possible to study specific antigen-antibody reactions in greater detail, eventually providing a deeper understanding of antigenic determinants and combining site structure. Moreover, the elucidation of the antigen-binding site has been greatly facilitated by the production of antibody variable domain fragments (Fv). As the volume of Fv fragments is half that of the Fab, Fv fragments generally crystallize in smaller asymmetric units and thus diffract to higher resolution.

By 1996 more than 50 structures of antibody fragments, free and complexed with antigen, had been determined by X-ray diffraction techniques. By far the

most widely studied antibodies have been of mouse origin. The mAbs were obtained after secondary responses and can be assumed to be highly specific – that is, they recognize only one antigen (and related, cross-reacting antigens sharing the antigenic determinant). Thus, their combining sites are uniquely defined by stereospecific contacts with the antigens. Several BALB/c mouse mAbs have now been studied by X-ray diffraction, including six which form complexes with hen egg-white lysozyme (HEL), two with influenza virus neuraminidase, one with HPr (a histidine-containing phosphocarrier protein), one with NC10 staphylococcal nuclease and four with anti-idiotopic antibodies. These results can be correlated with those of other crystallographic, immunochemical and sequence studies related to antigen and hapten recognition by specific antibodies. In most of the complexes above, the combining site is formed by amino acid residues from each of the CDRs of the L and H chains, although the H chain may in several cases contribute more contacts than the L chain. About 15 residues, mostly from the CDRs but including also one or two from the framework regions, are in contact with a similar number from the antigen. The general topology of the site is not that of a big cavity, but rather flat with interspersed depressions and protuberances that closely complement the surface topology of the antigenic determinant.

The nature of the chemical contacts made by the combining site includes charge bridges between ion pairs, hydrogen bonds and van der Waals interactions. If hydrogen bonds are inaccessible to solvent they should contribute appreciably to the stability of antigen–antibody interactions. In the complex of mAbs HyHEL-5 and D44.1 with HEL, two glutamic acid residues of the combining site interact closely with two arginines of the antigen. The crystal structure of HyHEL-5 complexed with a site-directed mutant of HEL (Arg68→Lys) demonstrated the specificity of electrostatic interactions. While generally considered a conservative mutation, the HEL mutant binds to HyHEL-5 with a 10^3 -fold reduction in affinity. The crystal structure demonstrated that lysine is unable to form both salt bridges to a HyHEL-5 glutamate, therefore the decrease in affinity of the HyHEL-5 reaction with the mutant HEL was ascribed to the loss of one hydrogen bond. Further evidence of the electrostatic complementarity defining antibody–antigen interactions came from the crystal structure of D1.3 complexed with turkey egg-white lysozyme (TEL). In this case, an important residue in the antibody–antigen interface (HEL Gln121) is replaced by a histidine. Gln121 makes two hydrogen bonds to carbonyl oxygen and amide nitrogen main-chain atoms of D1.3 V_L CDR-3 (O ϵ 1-Ser93 N; N ϵ 2-Phe 91 O). The orien-

tation of TEL His121 is such that its N ϵ 2 atom is positionally equivalent to the O ϵ 1 atom of HEL Gln121 and therefore unable to form a hydrogen bond to the amide nitrogen of D1.3 Ser93. D1.3 was observed to compensate for this difference in the electrostatic character of HEL121 by undergoing a flip of the main-chain peptide orientation such that the carbonyl oxygen of Trp92 is exposed at the interface, allowing formation of a hydrogen bond to TEL His121 N ϵ 2 (Figure 1).

Since hydrogen bonds and van der Waals interactions require a somewhat strict complementarity, they can be taken as the basis of antigen–antibody specificity. In the combining sites there is a high relative proportion of aromatic residues Tyr and Trp. Given their bulky size, these contribute a maximum of van der Waals contacts as well as affording the possibility of hydrogen bond formation to their polar atoms. The area of contact between antigen and antibody can be defined as that which becomes inaccessible to solvent after the formation of a complex. The surface buried by protein antigens is of about 600 Å² and higher, compatible with the requirements for the formation of a stable complex. This observation is in agreement with that made in other protein-interacting systems in which subunits make contacts through a closely packed interface occupying a large surface area. The crystal structure of a Trp→Asp mutation of D1.3

Figure 1 Conformational differences in antibody D1.3 V_L CDR3 induced by differing antigen side-chains. HEL residue Gln121 makes two main-chain hydrogen bonds; to the carbonyl oxygen of D1.3 V_L Phe91 and to the amide nitrogen of D1.3 V_L Ser93. Replacement of the glutamine by histidine in TEL induces a conformational change in the backbone of V_L CDR3 which allows the formation of a hydrogen bond between the histidine and the carbonyl oxygen of V_L Trp92. (See also color Plate 8A.)

exemplifies the importance of interacting surface complementarity and van der Waals interactions. The V_L Trp92→Asp mutation results in a 10^3 reduction in the affinity of D1.3 for HEL. Trp92 makes extensive van der Waals contacts with the antigen. With the substitution of Asp about 150 Å² of surface area are lost to the antibody-antigen complex, resulting in the reduction of affinity (Figure 2).

While a few buried water molecules have been reported in other antibody-antigen complexes, the D1.3-HEL complex contains a large number of bound water molecules which bridge the antibody and antigen. This water contributes to the stability of the antibody-antigen complex in two important ways: 1) the network of water molecules contributes to a favorable free energy of complex formation by mediating hydrogen bonds between antibody and antigen; and 2) the water molecules fill cavities in the interface which are destabilizing to complex formation (Figure 3).

No major conformational change seems to take place at the antibody site upon the binding of antigen. Small rearrangements of side-chains and CDR loops have been observed, particularly upon the binding of small antigens, most notably peptides, as well as relative displacements of V_H and V_L . Thus, antibody-antigen complexes can be viewed as a form of 'lock-and-key' association and small displacements can provide potential diversity in the conformation of the

Figure 2 The effect of a Trp→Asp mutation on the interaction surface area of the D1.3-HEL complex. A thin slice through the buried surface of the wild-type D1.3-HEL complex (dots) and the mutant D1.3-HEL surface (solid line) demonstrates the loss of interaction surface area in the mutant complex. A 150 Å² loss in surface area accounts for the reduction in affinity of the mutant D1.3-HEL reaction. (See also color Plate 8B.)

Figure 3 (A) Hydrogen bonding network of the D1.3-HEL interface mediated by bound solvent molecules; 25 water molecules form hydrogen bonds linking the antibody and antigen, directly or through other water molecules. (B) Water molecules in contact with the D1.3-HEL buried surface. Including the 25 bridging water molecules, nearly 50 solvent sites are in contact with the buried surface defined by the D1.3-HEL interface. Many of these water molecules fill internal cavities, further stabilizing the complex. (See also color Plate 8C and D.)

combining site and, perhaps, a mechanism by which the site could adapt to an antigenic determinant without large loss of entropy.

Molecular modeling of combining sites

Modeling of the CDRs of antibodies of unknown three-dimensional structure was attempted in several

laboratories, using different energy minimization and computer graphics approaches. The proposed models were subsequently compared with the determined crystallographic structures. The apparent occurrence of 'canonical structures' for most of the CDRs allowed successful approximation of the folding of the main polypeptide chain for the unknown antibodies. Establishing the orientation of side-chains is generally beyond the reach of these procedures, although in several cases they were correctly predicted. The biggest problems for modeling are posed by 1) the less predictable structure of the CDR3 of V_H ; 2) the relative positioning of V_H and V_L ; 3) the difficulty in placing solvent molecules which could be tightly bound to the combining site or its surroundings and thus contribute to its conformational stability; and 4) predicting possible conformational change that may take place upon antigen binding. Modeling attempts have been partially successful in determining the conformation of some of the CDRs compared with those observed in the crystal structures of the complexes with antigen. Thus they suggest agreement with the experimental observation that there is no major conformational change in going from the uncomplexed to the complexed antibody-combining site.

Genetic engineering of antibody-combining sites

Site-directed mutagenesis experiments performed on an antilysozyme antibody showed that a double mutant V_L Glu28→Ser, V_H Lys56→Gln increased 8- to 9-fold its affinity for the antigen. One interesting conclusion of this work was that removal of electrostatically charged side-chains and their replacement by noncharged residues with hydrogen bond potential allows formation of additional hydrogen bonds with the antigen and leads to an increase in affinity. Certainly, a prime consideration in the production of genetically engineered antibodies is an improvement

in affinity for antigen. However, important questions are yet to be answered in this regard: 1) what are the structural mechanisms which lead to the increase in affinity, and 2) why don't the natural diversification mechanisms produce these same hypervariable sequences?

ANTIGEN-PRESENTING CELLS

Emil R Unanue, Department of Pathology and Center for Immunology, Washington University School of Medicine, St Louis, Missouri, USA

Antigen-presenting cells (APCs) refers to the leukocytes responsible for antigen presentation. These include three sets of cells – the mononuclear phagocytes, the Langerhans-dendritic cells and the B cells.

Other cells can be made to have APC function under special conditions.

Antigen presentation is an obligatory step in the recognition of protein antigens by the T cell lineage.

The APCs bear the molecules encoded in the major histocompatibility complex (MHC), the class I and II molecules. These MHC molecules bind peptides resulting from intracellular processing of the protein. The MHC-peptide complex constitutes the antigenic determinant, the epitope, that engages the T cell receptor. Thus APCs are essential cells for the initiation and maintenance of all T cell responses. (See Antigen Presentation via MHC Class I molecules and Antigen Presentation via MHC Class II molecules.)

APCs need to have several properties in order for them to be involved in presentation to CD4 and CD8 T cells: 1) the capacity to take up the antigen; 2) the capacity to internalize the antigen and process it; 3) the synthesis and expression of MHC class I and II molecules; 4) the expression of adhesion molecules, to promote and insure the APC-T cell interaction; and 5) the expression of costimulator molecules (i.e. those molecules that promote the growth and differentiation of T cells during antigen presentation) and the release of cytokines. The APC-T cell interaction affects both cells; it is symbiotic. The APC changes its biology, becoming activated both in the case of macrophages and B cells; and the T cells respond by entering cell cycle and/or expressing cytokine genes. The activation of T cells is a 'two signal' event, dependent, first, on the engagement of its antigen receptor by peptide-MHC complex (signal 1) and, second, on interactions with the costimulatory mol-

ecules (signal 2). The major cell interaction molecules are shown in Table 1.

Not all these properties are expressed to the same degree by all the APCs. The differentiation state of APCs, the environment of a given tissue and the nature of the antigen molecule influence APC function. The T cells may also vary in their requirements, depending on their natural history (i.e. unstimulated versus memory cells). Finally, the antigen molecules themselves dictate the extent to which one or another property becomes important, in three ways. First, the physical and chemical form of the antigen determines the extent of uptake by APCs. Whether the antigen is a small molecule or part of a complex structure like that of a bacterium or a virus makes a difference. In the former case the antigen may enter the cell by fluid phase or receptor-mediated endocytosis, while the latter case involves a phagocytic process with internalization of a large extracellular ligand. Along these lines the capacity to internalize a microbe is limited for some APC-like B cells, in contrast to macrophages. Second, the complexity of the antigen will determine the number of peptides derived from its component proteins that become available for binding to MHC proteins. There is no direct estimate of the number of peptides that can be occupied by an MHC molecule when dealing with a bacterium, a complex protein or a simple polypeptide. But the limited studies indicate that the more protein taken up by the APCs, and the more complex the protein,

Table 1 Molecules involved in APC-T cell interaction

APC	T cells	Interaction
Class I and II MHC molecules	T cell receptor for antigen (TCR)	Engagement of the TCR provides first signal for activation
Class I and II MHC molecules	CD8/CD4 molecules	Function to promote the interaction of TCR with peptide-MHC class I (CD8) or peptide-MHC class II (CD4)
ICAM-1 (CD54) ICAM-2 (CD102) ICAM-3 (CD50)	LFA-1	Major sets of adhesive molecules
LFA-3 (CD58) (in humans), CD48 (in mice)	CD2	Promotes cell interaction and costimulatory function
B7-1 and B7-2	CD28 CTLA-4	CD28 involved in early T cell activation while CTLA-4 inhibits activation
CD40	CD40L	Primarily involved in B7 cell activation → promotes B cell activation
Cytokines IL-1 α and β IL-6 IL-12 TNF IL-10	Cytokine receptors	Interaction Secretion of early cytokines promotes vascular and tissue responses. Secreted by macrophages and DCs. Release of IL-12 promotes T _H 1 differentiation. IL-10 inhibits the system
IFN γ receptor	IFN γ	IFN γ released early by T _H 1 cells promotes macrophage activation

the larger is the number of peptides bound to MHC molecules. Last, the capacity of an antigen to stimulate the APC is a major factor that may lead to the enhanced response to some microorganisms. Indeed, many bacteria trigger the induction of cytokines, costimulatory and adhesion molecules that markedly influence the T cell response. In contrast, bland protein antigens are considerably less effective.

The three main APCs

Brief comments on three main APCs now follow. Macrophages are ubiquitous cells found in most tissues. They are highly active in internalization of a wide range of proteins as well as microorganisms. The extent of expression of class II MHC molecules varies among macrophages of various tissues and also among species. For example, most human monocytes and macrophages express class II MHC molecules, and are active in presenting antigens; in contrast class II MHC molecules are expressed on only a percentage of macrophages in the mouse. Here the percentage of class II-bearing cells varies from most of spleen macrophages to just a few of peritoneal macrophages. Accordingly, antigen presentation varies among them. Regardless, macrophages from all species express high levels of class II MHC molecules after their exposure to interferon γ (IFN γ).

Macrophages are highly effective in presentation of proteins and bacteria, most likely as a result of their highly developed endocytic capacity. They take up proteins by fluid-phase pinocytosis and/or receptor-mediated uptake, i.e. by their binding to specific surface receptors. Macrophages have complement receptors and Fc receptors that enable them to take up opsonized antigens as well as surface receptors for denatured proteins (scavenger receptors) or glycosylated proteins (such as the mannose receptor).

Macrophages are also highly secretory cells. Some of the secretory products are important during antigen presentation and early inductive events. These include interleukin 1 α (IL-1 α) and IL- β , tumor necrosis factor α (TNF α), IL-12, IL-6, IL-8 and a number of other chemokines. This group of early cytokines has effects on T cells as well as on connective tissue and vascular cells and they are believed to be involved in the early inflammatory changes in immunity. Macrophages also express adhesive and costimulatory molecules such as ICAM-1 (CD54), B7-1 (CD80) and B7-2 (CD86), respectively. Their level of expression is increased, particularly after the uptake of microbial antigens.

The Langerhans-dendritic cells constitute a single lineage, abundant in the skin and epithelia and thymus-dependent areas of lymphoid tissues. Langerhans cells are part of the family of dendritic cells (DCs). In the epidermis they constitute about 2–8% of the cells and are found between the keratinocytes, where they were first identified by morphological studies. Langerhans-dendritic cells arrive by way of afferent lymphatics to the thymic-dependent areas of lymphoid organs. In the skin they represent the local APC that takes up antigen molecules that contact the epidermis and carry the antigen by way of the lymphatic circulation to the draining lymph nodes. For example, application of protein-reactive compounds to the skin, such as dinitrofluorobenzene, ultimately results in their binding to the class II MHC of the Langerhans-dendritic cells, and with it the subsequent activation of T cells in the lymph nodes. Ultraviolet irradiation of the epidermis results in their disappearance; if such sensitizing compounds are applied to such areas, no T cell activation takes place.

DCs originate from bone marrow precursors, circulate, and seed the different lymphoid tissue and epithelia. DCs and macrophages have similar progenitors, with monocytes being a common cellular stage prior to the differentiation of the two lineages. In culture, the immature DC can differentiate to a mature state by the action of two cytokines, granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-4.

Another important immunological reaction where Langerhans-dendritic cells participate is in the allograft reaction. Their high content of MHC proteins make the Langerhans-dendritic cells the most powerful allogeneic cell in immunizing the host. Langerhans-dendritic cells are found in variable amounts in the interstitial and connective tissue of most transplanted organs (including liver, kidney, heart and, of course, skin).

DCs constitutively express high levels of class II MHC proteins, which makes them very active as APCs and as stimulator cells in the mixed leukocyte reaction. Langerhans-dendritic cells are active in presenting proteins but their degree of internalization and processing of protein antigens varies as a function of their state of maturation. As with macrophages, they mature in their antigen-presenting capacity. For example, their antigen-presenting capacity is limited when freshly harvested from the epidermis or blood but improves upon brief culture, which is one of the criteria for defining immature and mature DCs. DCs can express costimulatory molecules and release early cytokines such as IL-12.

B cells have an important antigen-presenting func-

tion that forms the basis for their interaction with T cells. B cells bind the specific antigen by way of their membrane immunoglobulin, internalize it and process it to peptides that become bound to their class II MHC molecules. The encounter with T cells reactive to the peptides results in a reciprocal activation of both cells. B cells function best as APCs if they are first activated, as they express only small amounts of costimulatory and adhesion molecules in their resting state. *In vitro* B cells become active in antigen presentation upon culture with anti-immunoglobulin antibodies and cytokines such as IFN γ . Such treatment does not affect the level of class II MHC on B cells but increases the level of adhesion molecules, including ICAM and of B7-1 and B7-2. Expression of class II MHC molecules is constitutive in B cells. This basal level is increased by IL-4 but not by IFN γ .

APC-T cell interaction in tissues

The dynamics of the encounter in tissues between a cloned T cell and the APC bearing the peptide-MHC complex is not entirely known and may depend on a number of conditions. For example, a bacterium that enters a nonlymphoid tissue, the lung alveoli, will be taken up by alveolar macrophages and an inflammatory reaction ensues as the macrophages release early cytokines. This inflammatory reaction is conducive to the encounter between APCs and T cells. A different situation may develop when a contact-sensitizing molecule reaches the skin. Here the Langerhans cells located in the epidermis will take up the sensitizer and will now move via the afferent lymphatic to the draining lymph nodes. Thus, in this reaction part of T cell induction is in part mediated by the transport of the antigen directly to the lymphoid organs.

The anatomy of APC-T cell interaction in lymph nodes and spleen has been difficult to study. A network of APCs are found in the deep cortex of the lymph nodes where presumably the productive trapping of antigen and encounter with the T cell takes place. DCs constitute many of the 'interdigitating cells' found in histological examinations. The relative importance of, and the interplay among, the three APCs described above in a physiological immune response is not entirely understood. A likely scenario is one where antigen is first trapped by the macrophages and DCs of the thymus-dependent areas of lymphoid organs and there recruit and activate antigen-specific CD4 T cells. The subsequent stage envisions B cells binding the antigen molecule via their surface immunoglobulin and interacting with the activated CD4 T cells. In follicles and germinal centers B cells interact with the follicular dendritic

cells that bear antigen-antibody complexes on their surface. This interaction is part of the reactions that lead to B cell activation and differentiation.

The case of CD8 T cells

APCs are involved in the early activation of CD8 T cells by presenting peptides via class I MHC molecules. Once activated, the CD8 T cells will be able to interact and react with class I MHC-peptide complex presented in various target cells. Thus, in the antiviral response the first encounter that recruits and activates specific antiviral clones will be that of infected APCs (either macrophages or DCs) with the CD8 T cells. Once clonal expansion and activation takes place, the CD8 T cells can kill the virally infected target cells. APCs also have the ability to capture proteins from other cells (i.e. tumor antigens, alloantigens, for example) and process it into the class I MHC presentation pathway, a process that needs to be better defined in mechanistic terms. (See Antigen Presentation via MHC Class I Molecules.)

Most epithelial, vascular and mesenchymal cells do not express class II MHC molecules or costimulatory molecules; however, there are exceptions: thymic epithelium normally expresses class II MHC molecules, and some mucosal cells of the gastrointestinal tract and proximal tubular cells of the kidney also express some levels of class II MHC molecules. During inflammation, as a result of local IFN γ production, many cells are made to express class II MHC molecules. Whether this aberrant expression is involved in tissue autoimmunity needs to be settled. Tissue cells express limited amounts of costimulatory molecules which makes them poor APCs for initiating T cell activation.

ANTIGEN-SPECIFIC CELLS: ENRICHMENT AND ISOLATION

KGC Smith, Department of Medicine, University of Cambridge, School of Clinical Medicine, Addenbrooke's Hospital, Cambridge, UK

JE Layton, Ludwig Institute for Cancer Research, Melbourne Tumour Biology Branch, Post Office Royal Melbourne Hospital, Victoria, Australia

DM Tarlinton, The Walter and Eliza Hall Institute of Medical Research, Post Office Royal Melbourne Hospital, Victoria, Australia

Burnet, in his clonal selection theory of antibody formation, proposed that the precursors of antibody-forming cells carried receptors of unique specificity for a particular antigen. After 'selection' by antigen, the antigen-specific cell would proliferate and eventually give rise to a clone of antibody-secreting cells. The antibody produced would be specific for the original antigen. Given the large number of different antigens in the environment, for any single antigen the frequency of antigen-binding cells would have to be very low, and an individual antigen-binding cell should bind only one antigen. The validity of the clonal selection theory was first demonstrated for B lymphocytes, but was subsequently shown to be true for T lymphocytes, which are also antigen specific.

Antigen-binding cells were first demonstrated and enumerated with large particulate antigens such as bacteria and red blood cells. Binding of soluble antigen by lymphocytes was first visualized by Naor and Sulitzeanu, who used ^{125}I -labeled albumin and autoradiography. The first antigen-binding lymphocytes studied were B cells, which recognize antigen with a unique antigen receptor comprising surface immunoglobulin. The fact that B cells bear this antigen receptor which recognizes antigenic epitopes in their native form has made isolation of antigen-specific B cells relatively successful. In contrast, T cells recognize antigen after processing to peptide form and in the context of major histocompatibility complex (MHC) molecules, and do not bind native antigen. This has made their isolation considerably more difficult. Problems with the isolation of antigen-specific cells are compounded by the relative scarcity of these

cells. Even at the height of the B cell response to haptens such as (4-hydroxy-3-nitrophenyl)acetyl (NP) in the mouse, the antigen-specific B cells constitute no more than 1% spleen cells, declining to <0.01% of cells in the memory cell population. The other problem is that antigen-specific lymphocytes may differ only subtly from their colleagues, and detection of this subtle difference is critical to their isolation.

Early attempts to deplete antigen-specific cells were made to provide evidence in support of the clonal selection theory. These techniques are no longer in common use and will be considered only briefly. Detailed study of the immune response to both experimental immunogens and to pathogens is greatly enhanced by the isolation of antigen-specific lymphocytes. Techniques for such enrichment and isolation are more advanced for B cells, which will be considered first. Recent techniques employed for the isolation of antigen-specific T cells will then be examined.

Enrichment and isolation of B lymphocytes

Depletion

The first attempts to deplete antigen-binding cells were made by Wigzell and colleagues using antigen-coated beads in affinity columns, which depleted antigen-binding cells but also a significant number of nonspecific cells. An alternative approach was to deplete antigen-specific cells by allowing them to bind radioactive antigen of high enough specific activity to kill them; a technique sometimes referred to as 'antigen suicide'. Ada and Byrt demonstrated

that incubation in the cold of lymphoid cells with ^{125}I -labeled T-independent antigens specifically abolished the response of these cells to the unlabeled antigen on adoptive transfer into irradiated syngeneic recipients, establishing that antigen-binding B cells were the precursors of antibody-forming cells. These experiments provided strong support for the clonal selection theory but did not yield purified populations of antigen-specific cells for further study. Such methods are no longer widely used.

Enrichment: historical methods

A number of approaches have been taken to enrich lymphocyte populations for antigen-specific cells. Some are now of historical interest only. Such techniques include the use of affinity matrices and columns. Two major problems with these modalities were nonspecific adsorption of cells to affinity matrices and difficulty in recovering viable, functional cells after interaction with antigen.

Another early method for isolating antigen-specific cells was the use of hapten–gelatin-coated Petri dishes ('panning'). Cell suspensions were added to the dishes, binding of hapten-specific B cells occurred, unbound cells were washed off and bound cells recovered by melting the gelatin layer at 37°C. A major disadvantage of this method was its relatively low cell yield, but combined with limiting dilution assays, it was a useful method for studying antigen-specific B cell activation.

Rosetting has also been used to enrich for antigen-specific B cells. For example, haptenated horse red blood cells (HRBCs) were allowed to bind to hapten-specific B cells, forming rosettes. The rosettes could then be separated from nonrosetted cells by buoyant density and/or sedimentation velocity centrifugation, and the HRBCs removed from the antigen-binding cells by protease digestion, followed by overnight culture of the cells to allow for receptor regeneration.

Enrichment: 'Pre-enrichment' by depletion of nonantigen-specific cells

Partial purification or enrichment of antigen-specific cells subsequently allows more rapid and accurate isolation of these cells by more time-consuming or expensive procedures, such as fluorescence-activated cell sorting (FACS: see below). The removal of unwanted cells can be achieved by physical means, such as by taking advantage of the propensity of T cells to bind to nylon wool columns or of macrophages to adhere to plastic. Depletion of unwanted cells using complement fixation is a commonly used and effective technique. To enrich for immunoglobulin G-positive (IgG⁺) B cells, for example, spleen cells are cultured in a cocktail of antibodies against

T cells (e.g. anti-CD3), macrophages and other B cells (e.g. anti-IgM). Provided the chosen antibodies fix complement efficiently (IgM antibodies are best) and have been properly titrated to reduce nonspecific killing, considerable enrichment and high yields can be achieved. Similar cocktails of antibodies conjugated directly or indirectly (via biotin-avidin) to magnetic beads can be used to remove unwanted cells, as cells binding the paramagnetic beads will stick to steel wool in a column or to the side of a container when a magnetic field is applied, while the desired cells will pass through the column (Figure 1). A potential hazard of this technique is the risk of saturating the column: if the surface area of the steel wool is inadequate to bind the number of cells to be depleted they too will pass through the column causing substantial contamination. One advantage of these 'negative selection' methods of enrichment is that they do not require antibody binding to, and thus potential activation of, the antigen-specific cells.

Enrichment: positive 'pre-enrichment'

Paramagnetic beads can also be used to enrich for antigen-specific B cells in a 'positive' fashion. If, for example, the antigen-specific B cells have a characteristic immunoglobulin isotype (such as the γ heavy and λ light chains in the response to NP) antibodies to these can be used to attach magnetic beads to the cells of interest. These cells will then attach to the column as described above, and can be washed by passage of medium through the column, followed by their removal by flushing after withdrawing the column from the magnetic field (Figure 1). Saturation of the column will not result in impurity of the resulting population, but only a reduced yield. In the example above, enrichment of spleen cells using anti-IgG1 and paramagnetic beads can result in a 40-fold enrichment for anti-NP-specific B cells, with a proportionate reduction in the flow cytometry time needed to complete the purification.

One problem with positive enrichment using these columns is nonspecific adhesion of dead cells to the column. If this is a problem, dead cells may have to be removed in a separate initial step, for example using density gradient separation. Direct conjugation of antigen to paramagnetic beads is currently being attempted which should improve isolation of antigen-specific cells by this method.

The flow cytometer can itself be used to pre-enrich cells prior to a further round of flow cytometry. Very rapid sorting by FACS results in a predictable number of errors and therefore impurity. Substantial enrichment is nonetheless achieved during this very rapid sorting, and the time needed for the subsequent

Figure 1 Schematic representation of the use of paramagnetic beads for 'positive' enrichment. (A) The desired cells are labeled with a biotinylated antibody, washed, then attached to avidin beads. (B) Labeled cells are retained when a magnetic field is applied, and unwanted cells are washed through. The desired cells are then recovered after removal of the column or tube from the magnetic field.

slower and more accurate sort is reduced resulting in an overall saving of time.

Isolation: fluorescence-activated cell sorting

FACS provides the most reliable and accurate means of purifying antigen-specific B cells. B cells can be identified by a number of markers, but the ability to detect binding of a specific antigen is crucial to identifying antigen-specific cells. Initial success using this method was achieved by Hayakawa and colleagues, who immunized mice with the fluorescent protein phycoerythrin (PE), later isolating PE-binding B cells on the FACS. This technique was later advanced by Lalor, McHeyzer-Williams and Nossal, who identified NP-specific B cells by detecting binding of NP conjugated to allophycocyanin, allowing further dissection of a well-characterized stereotypic immune response.

A major drawback of this technique has been the time (and therefore expense) taken to sort substantial number of cells if these are very rare. This can now be largely overcome by using one or a combination of the pre-enrichment techniques described above.

Another advance has been the advent of techniques allowing analysis of single cells, which removes the need to sort large numbers of cells. For example, a polymerase chain reaction (PCR)-based strategy can be used to amplify single genes from cDNA which can subsequently be sequenced. This has allowed analysis of patterns of somatic hypermutation in very rare subpopulations of antigen-specific B cells, such as the bone marrow antibody-forming cells described below.

Another major problem is the potential difficulty in ensuring the purity of very rare populations of cells, as relatively few cells which are incorrectly sorted can reduce the purity of such populations dramatically. This has been overcome by making maximal use of the number of detection parameters available on modern FACS machines. Consider the example of the isolation of NP-specific bone marrow antibody-forming cells shown in Figure 2. First, all cells which do not have the forward and side scatter characteristics (which measure size and 'complexity' respectively) of lymphocytes are excluded. One channel is then used to identify and exclude unwanted

Figure 2 Identification of NP-specific antibody-forming cells in the bone marrow after 14 days of the primary immune response. (A) Cells staining for IgM, IgD and Gr-1 and propidium iodide were excluded. Antibody-forming cells were identified by their expression of syndecan. (B) This population was further partitioned into cells expressing IgG1 and able to bind the immunizing hapten NP, coupled to a fluorochrome. In the example shown, the NP-specific antibody-forming cell population represents 0.003% of nucleated bone marrow cells. Boxes indicate the criteria used for sorting cells for V_H gene sequencing.

cells. Antibodies to IgM, IgD and the myeloid-macrophage lineage marker Gr-1 are conjugated to PE, and dead cells are labeled with propidium iodide (which fluoresces in the PE channel), and all of the cells so labeled can be excluded from further analysis (a 'dump' channel). The addition of a dump channel to a single positive selection channel can decrease nonspecific contamination to less than 1 in 10^6 cells. Two further antibodies identify markers characteristic of the cells required – syndecan (a marker of antibody-forming cells, in the fluorescein channel) and surface IgG1 (in the Texas Red channel). Finally a sixth parameter is used to ensure antigen specificity, that is, the ability of the $\text{IgM}^- \text{IgD}^- \text{Gr-1}^- \text{syndecan}^+ \text{IgG1}^+$ cells to bind the original immunizing antigen NP bound to allophycocyanin. The probability of a nonspecifically staining cell having the same characteristics as the required cells in all six parameters is so low that populations of antigen-specific cells as rare as 1 in 200 000 cells can now be reliably and consistently sorted to >95% purity, even in the absence of pre-enrichment (see Figure 2).

Isolation: histology

The groups of Kelsoe, Rajewsky and others have recently isolated antigen-specific B (and germinal center T) cells by micromanipulation of single nuclei from histological sections. While this can only isolate small numbers of nuclei for PCR analysis, it does permit correlation of the molecular information obtained by PCR with the exact location of the cell in a stained histological section. This has allowed

elegant analyses to be performed of the development of the postantigenic B cell response which would not have been possible using conventional techniques.

Isolation: transgenic mice

Another approach to isolation of antigen-specific cells is the creation of mice bearing transgene-encoded antigen receptors of known specificity. Well-known examples are the mice transgenic for a T cell receptor specific for the male HY antigen, and those transgenic for immunoglobulin binding hen egg lysozyme. Thus the vast majority of the lymphocytes in such mice are of known specificity. This avoids the need to isolate rare cells, but requires careful interpretation of results since they have been obtained from mice with a markedly skewed lymphocyte repertoire.

Enrichment and isolation of T lymphocytes

T cell receptors (TCRs) recognize processed antigen (peptides) in the context of MHC. It is therefore currently not possible to isolate antigen-specific T cells by detecting antigen binding using the FACS or paramagnetic bead technology. Clearly, however, all the pre-enrichment techniques described above for B cells also apply to T cells. A traditional approach to isolating antigen-specific T cells has been to stimulate T cell populations with antigen and subsequently to clone cells activated by that antigen. The option is then available to make hybridomas from single cloned antigen-specific T cells.

A number of novel approaches have been taken to the isolation of antigen-specific T cells in the absence of an *in vitro* activation and cloning step. Monoclonal antibodies have been raised which recognize a single clonotype of TCR and which, in principle, could be used to identify antigen-specific cells in responses utilizing this clone. Some T cell responses use a limited and well-defined TCR, and detection of these cells by FACS can serve as the basis for identifying antigen-specific cells. A recent example is the identification by McHeyzer-Williams and Davis of T cells responding to pigeon cytochrome C in draining lymph nodes after immunization by staining for V α 11V β 3 TCR.

ANTIGEN CLEARANCE

Antony J Cutler and Kevin A Davies, Rheumatology Unit, Royal Postgraduate Medical School, Hammersmith Hospital, London

The clearance of exogenous antigens constitutes one of the primary functions of the immune system. Antigens are mainly eliminated by the cells of the fixed mononuclear phagocytic system. The mechanism of removal depends on the biological and physico-chemical properties of the antigen concerned, its mode of presentation to the immune system, and its ability to elicit a specific humoral or cellular immune response.

Antigen clearance by immune complex formation

Immune adherence, complement receptor type 1 and immune complex transport

Immune complexes that form within or enter the circulation may have to travel some distance around the body before reaching one of the organs of the

fixed mononuclear phagocytic system. The majority of immune complexes travel through the circulation bound to receptors on the surface of circulating cells rather than free in plasma. On arrival in the fixed mononuclear phagocytic system, they are transferred from the carrier cell to fixed macrophages.

The binding of immune complexes to receptors on carrier cells was first described for complement-coated microorganisms many years ago. Pneumococci injected intravenously into immune rabbits were shown to cluster around platelets in blood taken by cardiac puncture, and it was also shown in early studies that the serum of rats which had recovered from infection with *Trypanosoma brucei* would cause blood platelets to adhere to *T. brucei* *in vitro*. It was subsequently found in humans and other primates that erythrocytes, rather than platelets were the main cell in blood to which opsonized trypanosomes would bind. The role of complement

in mediating these binding reactions was initially suggested by Kritschewsky and Tscherikower, working in Moscow, who observed that sera inactivated at 55°C would not mediate binding. Subsequently, it was shown that erythrocyte adherence reactions could be abolished by heat treatment of sera and by dilute ammonia (inactivating C4). The observation that treatment of serum with cobra venom factor (CVF) prevented adherence reactions showed an essential role for C3. Nelson and colleagues in the 1950s rediscovered this 'immune adherence' phenomenon in studies of the reactions between human erythrocytes and specifically-opsonized treponemes and pneumococci.

Our present understanding of the immune adherence phenomenon followed the isolation by Fearon of the molecule responsible for the adherence reactions of human erythrocytes, the C3b/iC3b receptor (complement receptor type 1, CR1, CD35). This receptor bound large immune complexes and was shown to play a role in the transport of soluble immune complexes *in vivo* in primates. CR1 is a receptor for C3b and iC3b with diverse activities including: 1) the uptake by phagocytic cells of C3b- and iC3b-coated immune complexes and particles; 2) acting as a cofactor for factor I-mediated cleavage of C3b to iC3b and then C3dg; and 3) acting as a transport molecule for immune complexes, both soluble and particulate. Relevant to antigen clearance is the role of CR1 as a transport molecule.

There is considerable interspecies variation of the sites of expression of CR1. In humans and other primates the majority of CR1 in the circulation is located in a clustered form on erythrocytes. The actual number of CR1 molecules per erythrocyte is extremely low, varying between 50 and approximately 1000 receptors per cell in humans. This compares with 5000 to 50 000 receptors per neutrophil depending on the state of cellular activation. However, in spite of this unfavorable comparison, red cells play an important role in the binding and transport of C3b- and iC3b-coated immune complexes and particles through the circulation, partly as a result of the vast numerical majority of red cells over other cell types (approximately 1000 erythrocytes for every neutrophil) and partly as a consequence of the clustered nature of CR1 on erythrocytes which promotes very high avidity interactions with ligand, in comparison to neutrophils and lymphocytes on which the receptor is expressed as cell surface monomers. In other species a hybrid molecule sharing the activities expressed by human CR1 and CR2 is expressed on leukocytes and platelets, and no complement receptor is expressed on erythrocytes.

***In vivo* studies of soluble immune complex processing in animals**

The major site of clearance of immune complexes is the fixed mononuclear phagocytic system. In most species, including lagomorphs, primates and rodents, the liver and spleen are the primary sites in the circulation in which tissue macrophages are located. However, pulmonary intravascular macrophages are also found in pigs, cows, sheep, goats and cats, and these have been shown to be important both in the clearance of particles and soluble immune complexes.

In lagomorphs and rodents soluble immune complexes, injected intravenously, were predominantly removed in the liver and spleen, as in humans, but the complexes were not transported in the circulation bound to erythrocytes, which in these species do not bear CR1. Platelets in these species bear C3b receptors and rapid *in vivo* binding of immune complexes to platelets has been observed following intravenous injection.

Evidence for the importance of antigen as well as antibody in determining the clearance kinetics of immune complexes came from studies of the clearance in mice of immune complexes containing as antigen either orosomucoid or ceruloplasmin or their desialylated derivatives. The asialo-orosomucoid-containing complexes were cleared 20-fold more rapidly than those containing the sialylated molecule, and blocking studies showed that the rapid clearance phase was mediated by a hepatocyte carbohydrate receptor.

Antigen clearance by immune complex formation in primates was first shown in a series of experiments in baboons. Large radiolabeled immune complexes comprising BSA/anti-BSA were initially employed. Following intra-aortic infusion, these complexes bound rapidly to erythrocytes, and were subsequently cleared during transit through the hepatic, but not renal circulation. The effect of complement-depletion was evaluated by CVF treatment. In decomplemented animals, the immune complexes did not bind to red cells, and were cleared more rapidly, depositing in other organs, including the kidney. It was subsequently shown that immunoglobulin A (IgA)-containing complexes, which fixed complement poorly, also failed to bind to baboon erythrocyte CR1, were cleared rapidly, and localized in other organs.

The liver and spleen are not the main sites of immune complex clearance in all species. In pigs, ruminants and cats, the anatomy of the fixed mononuclear phagocytic system is different and intravascular pulmonary macrophages play an important

role in the clearance of immune complexes and also in the clearance of bacteria. Immune complex processing in pigs was associated with a fall in peripheral blood mononuclear cell numbers not seen in studies of immune complex clearance in humans.

***In vivo* studies of soluble immune complex processing in humans**

The *in vivo* processing of exogenously administered soluble immune complexes in humans has been studied in three main model systems. These are heat-aggregated IgG, tetanus toxoid (TT)/anti-TT, and hepatitis B surface antigen (HBsAg)/anti-HBsAg immune complexes. ^{125}I -labeled heat-aggregated IgG injected intravenously into normal subjects was shown by γ scintigraphy to be cleared in the liver and spleen. The complement- and CR1-dependent natures of soluble immune complex clearance mechanisms were first studied *in vivo* using ^{125}I -labeled tetanus toxoid/anti-tetanus toxoid complexes. Either native complexes or complexes preopsonized *in vitro* with autologous serum were injected into normal volunteers, and into patients with immune complex disease or hypocomplementemia. Immune complexes bound to erythrocyte CR1 receptors in a complement-dependent manner, and CR1 number correlated with the level of uptake. Two phases of clearance were seen. In subjects with low CR1 numbers and hypocomplementemia there was a very rapid initial disappearance of immune complexes. The second phase of clearance was approximately mono-exponential, and the observed elimination rate correlated inversely with CR1 numbers and the binding of immune complexes to red cells. Similar *in vivo* studies of soluble immune complex clearance have been performed using ^{123}I -labeled HBsAg/anti-HBsAg immune complexes. The fate of these immune complexes was followed by blood sampling and γ scintigraphy to define the site and kinetics of processing in normal subjects, patients with systemic lupus erythematosus (SLE) and a single patient with homozygous C2 deficiency. In normal subjects, complexes were cleared in the liver and spleen, with a median clearance half-time of 5 min. At 10 min around 40% of the injected complexes were bound in the liver in normal subjects. The majority of the injected complexes bound to red cell CR1 at 2 min. In all subjects there was a very close correlation between *in vivo* binding to red cells and CR1 number. In hypocomplementemic SLE patients there was more rapid initial immune complex uptake into the liver, but subsequent re-release of complexes back into the circulation. Defective splenic immune complex uptake was also observed in these patients, and repletion experiments in a C2-deficient subject

showed that the splenic uptake of soluble labeled HBsAg/anti-HBsAg immune complexes was entirely complement dependent. The early work of Pepys and Klaus and colleagues demonstrated that complement is critical for facilitating the localization of certain antigens to follicular dendritic cells, and for the development of a memory immune response. Defective antigen processing and splenic localization of immune complexes in hypocomplementemia may be a factor in the development of autoimmunity in SLE.

A significant criticism of all of the studies of immune complex processing described above is that they all involve large immune complex prepared *in vitro* in the absence of complement. Physiologic antigen clearance *in vivo* will frequently involve the formation of complexes between an exogenous antigen and pre-existing antibody. A number of attempts have been made to model this situation. The successive infusion of human anti-dsDNA antibodies and dsDNA into monkeys and rabbits led to rapid formation of immune complexes which bound to red cell CR1. The formation and fate of immune complex formed *in vivo* in human subjects receiving radio-immunotherapy has also been studied. Successive administration of a radiolabeled mouse antitumor antibody and a human anti-mouse antibody resulted in the formation of immune complexes comprising the two antibody species. Rapid clearance of complexes was observed with binding of approximately 10% of the complexed material to CR1. Systemic complement activation, and a 30% fall in erythrocyte CR1 numbers were observed. External γ counter monitoring indicated that clearance took place primarily in the liver.

Clearance of an autoantigen – erythrocytes

The class of antibody bound to the antigen influences the site of clearance of particulate immune complexes. This is illustrated by studies of autoimmune hemolytic anemia. Cold agglutinin disease is mediated by IgM anti-I antibodies, which stimulate efficient classical pathway activation and fixation of C4 and C3 to erythrocytes. The role of anti-I and complement in mediating cell lysis was first studied in a rabbit model. IgM cold agglutinin was injected into C3-depleted and C6-deficient rabbits. The latter developed thrombocytopenia, neutropenia and a fall in hemoglobin, with only minimal hemoglobinemia, but a sharp fall in plasma C3. Circulating red cells could be readily agglutinated with antibodies to C3, and *in vivo* immune adherence of platelets to red cells occurred. In the C3-depleted animals injection of the anti-I IgM produced no significant hematological changes. The fate of erythrocytes in cold agglutinin disease has been modeled in primates using

radiolabeled cells coated with an IgM cold agglutinin. The liver was the main site of red cell uptake. Transient retention of cells in this organ occurred, thought to be mediated by reversible binding to complement receptors. In patients with cold agglutinin disease, circulating red cells are characterized by a change to a microspherocytic form, accompanied by the presence of many thousands of C3dg molecules bound per cell. Three possible conclusions may be drawn from these observations. The first is that phagocytic uptake of erythrocytes which have bound IgM and fixed C3 and C4 is very inefficient. The second is that, during the transient retention of red cells in the liver, it is probable that the C3 is catabolized to C3dg and erythrocyte shape changes occur. The third is that there is no clearance receptor in the circulation for C3dg-coated particles.

By contrast, in warm hemolytic anemia mediated by IgG, uptake of erythrocytes occurs predominantly in the spleen by Fc-dependent pathways. ⁵¹Cr-labeled incompatible red cells, transfused into recipients with noncomplement fixing antibodies, were removed from the circulation monoexponentially with a half-time of 18–20 min. Splenic uptake was also monoexponential, with a similar half-time. No uptake was detectable elsewhere, notably in the liver. As the spleen exclusively removed cells, and this organ receives only a small fraction of the cardiac output, it was reasoned that the splenic extraction efficiency was very high. It was subsequently demonstrated that the site of sensitized red cell destruction was dependent on the degree of antibody coating, with more heavily coated cells being destroyed predominantly by the liver.

Radiolabeled erythrocytes, coated with IgG, have been extensively studied as a probe of the capacity of the mononuclear phagocytic system to remove particulate antigens. In humans and other species, these cells are cleared largely in the spleen. The mechanisms whereby this probe exhibits primarily splenic clearance, while cells coated with IgM and C3, and soluble immune complexes, discussed above, localize predominantly in the liver, are poorly understood. Tissue macrophages in the liver and spleen bear both Fc and complement receptors (CR1, CR3 and CR4), while follicular dendritic cells within the spleen and lymph nodes also bear CR2. The Fc receptors primarily involved in interaction with complexes or aggregated immunoglobulin are the relatively low-affinity receptors FcγRII and FcγRIII. The binding and retention of an immune complex within the liver and spleen will partly reflect the specific receptor(s) with which it interacts.

Nonclonal receptors in antigen clearance

Growing evidence suggests that initial interaction of pathogens with the innate immune system can initiate and direct the development of the adaptive immune response. As discussed, pathogens opsonized by serum proteins are phagocytosed and cleared from the body by cells of the immune system. In addition, germline-encoded receptors with the capacity directly to recognize nonopsonized microorganisms have been identified on cells of the innate immune system. Janeway proposed that such nonclonal receptors, termed 'pattern-recognition molecules', bind common constituents of pathogenic microorganisms, providing a first line of defense in the preimmune host. The wide spectrum of molecules recognized would not be expressed on the surface of normal cells, thus allowing discrimination of non-self from self. Scavenger receptors, CD36, CD14, and mannose receptors have been proposed as candidate pattern-recognition receptors.

Scavenger receptors

Initially identified for the ability to bind low-density lipoproteins (LDLs), macrophage scavenger receptors (SRs) were found to exhibit broad polyanionic ligand binding specificity, a characteristic of pattern-recognition molecules. Three independent subclasses of receptor, SR-A, B and C have been described, with expression limited to monocytes, macrophages and hemocytes. Type I and II class A SRs bind to and remove endotoxin (lipid A of LPS) from plasma. Whole gram-positive bacteria and lipoteichoic acid (LTA), a ubiquitous gram-positive cell wall constituent, were shown to be additional ligands for type I SR-As. A third recently described SR-A, 'MARCO', expressed on splenic and lymph node macrophages was also reported to interact with *E. coli* and *Staphylococcus aureus*. A primary function of SR-As on macrophages, monocytes and hemocytes appears to be the clearance of toxic shock-inducing microbial cell surface constituents and pathogenic microorganisms from the body.

The rapid phagocytosis of damaged and apoptotic cells prevents the release of noxious intracellular molecules into the body and prevents exposure of the adaptive immune system to unseen components of self. Ailing cells express surface molecular structures not characteristically found on normal cells. Growing evidence supports the proposal that SRs function in the clearance of apoptotic and damaged cells. COS cells acquired the capacity to phagocytose apoptotic cells when transfected with the class B SR CD36. CD36 has also been implicated in mediating the

Figure 1 The structure of mannose-binding lectin.

clearance of *Plasmodium falciparum*-infected red blood cells, apoptotic neutrophils and leukocytes, and as a rhinovirus receptor. Recent reports indicated that class A SRs facilitated the uptake of

oxidatively damaged erythrocytes. The uptake of approximately 50% of apoptotic thymocytes *in vitro* was recently reported to be SR-A dependent, a finding yet to be demonstrated *in vivo*. Therefore, SRs appear to be candidate receptors for molecules expressed on damaged or apoptotic cells.

CD14

CD14 is a 55 kDa glycoprotein found as a glycosyl phosphatidylinositol (GPI)-anchored species on monocytes, macrophages and as an abundant protein in plasma. It interacts with soluble lipopolysaccharide (LPS) released from gram-negative bacteria in combination with a plasma protein, LPS-binding protein (LBP). Blockade by mAb or elimination of CD14 expression by gene knockout technology lowered the sensitivity of animals to LPS by 100–10 000 fold. CD14 exhibits many characteristics of a pattern-recognition receptor. The binding of many

Figure 2 Adaptive and innate immune mechanisms of antigen clearance.

different components of both gram-negative and gram-positive bacteria to macrophages and monocytes has been shown to be CD14 dependent. Indeed, a nonmonocytic cell line acquired the capacity to bind intact gram-negative bacteria following transfection with the CD14 gene. Furthermore, CD14-dependent phagocytosis of whole gram-negative bacteria was recently demonstrated *in vitro*.

CD14/bacterial interaction induces activation of macrophages. The cytokines produced act to recruit lymphoid cells and possibly direct the resulting adaptive immune response. A recent report has suggested that interleukin 12 (IL-12) production following macrophage contact with LTA from gram-positive bacteria can be CD14 dependent. IL-12 is a potent stimulator of T_H1 CD4 T cells. Therefore CD14-dependent signals might exert an early influence on the nature of any resultant adaptive immune response. Furthermore, the release of the potent inflammatory cytokines tumor necrosis factor α (TNF α), IL-1 β and IL-6 following bacterial activation of macrophages appears in part to be CD14 dependent. These mediators recruit phagocytic cells, principally neutrophils, to the site of infection which may enhance the clearance of antigen and influence disease progression. However, if uncontrolled, these same cytokines can contribute to the development of sepsis syndrome in humans. CD14 plays a major role in this disease as CD14-deficient mice are highly resistant to toxic shock. Numerous anti-LPS antibody reagents have been used clinically in an attempt to modify the development of septic shock in infected patients, with to date disappointing results, presumably because the cytokine-mediated physiological response responsible for the syndrome is already established in most cases by the time the therapeutic agent is administered.

Mannose receptors

The mannose receptor is a well-characterized macrophage membrane lectin expressed on tissue macrophages throughout the body but not on circulating monocytes. Evidence strongly suggests that mannose receptors play a role in the clearance of pathogens. The mannose receptor is known to bind to mannose- and fucose-containing microorganisms by carbohydrate recognition domains. Numerous reports have detailed mannose receptor recognition of yeast, bacteria and certain protozoa. Furthermore, non-phagocytic COS cells gained the capacity to bind and ingest microorganisms following transfection with mannose receptor genes, a clear indication that the mannose receptor is a professional receptor for phagocytosis. The engagement and phagocytosis of microorganisms by the macrophage mannose recep-

tor actively stimulates the release of secretory products including IL-1, TNF α and reactive oxygen intermediates, further enhancing the clearance of antigen.

It is of interest that dendritic cells express the mannose receptor and a membrane lectin (DEC-205) with structural similarities and binding specificities to that of the macrophage mannose receptor. These receptors have a potential role in the enhancement of the capture, processing and presentation of antigen to the adaptive immune system by dendritic cells.

Mannose-binding protein/lectin (MBP/L)

MBP/L is a soluble serum protein and belongs to the collectin family of proteins, which is becoming increasingly recognized as an important component of the nonclonal immune system. MBP/L is a C-type lectin (Figure 1) which mediates calcium-dependent binding of certain carbohydrates. The protein recognizes mannose and N-acetylglucosamine residues on gram-positive and negative bacteria as well as yeast and certain parasites, protozoa, mycobacteria and viruses. Acting in concert with an MBP-associated serine protease (MASP), MBP/L can activate the classical complement pathway by cleaving the C4 and C2 molecules generating C4b2a complexes with C3 convertase activity. Indeed, MBP interaction with rough *E. coli* induces complement activation and bactericidal lysis. MBP can also act as an opsonin, either by inducing C3b deposition and subsequent clearance by phagocytic cells or independently by binding to C1q receptors.

The different mechanisms of antigen clearance we have described, involving both the innate and adaptive immune systems are summarized in Figure 2.

ANTIGEN, ENTRY INTO THE BODY

Taede Sminia and **Georg Kraal**, Department of Cell Biology, Medical Faculty of Vrije University, Amsterdam, The Netherlands

The epithelia of the skin and the mucous membranes of the respiratory, gastrointestinal and urogenital tract represent an extensive surface area. They are constantly exposed to a great variety of microorganisms and other antigenic substances. The skin constitutes a strong mechanical (keratin layer) and physiological (gland products, in particular sebum) barrier towards antigen. In the mucous membranes, which are only covered by a thin specialized epithelium, other mechanisms such as ciliary function and nonspecific and antimicrobial factors (e.g. mucin and lysozyme) are involved in preventing or combating infections. In addition, specific immune reactions play a part. The hallmark of specific mucosal immunity is the production and action of secretory immunoglobulin A (sIgA), which displays its functions at the mucosal surface ('outside' the body), and of effector T cells. Thus, the epithelia of the skin and the mucous membranes are primarily engaged in antigen exclusion; only under pathological conditions (e.g. wounding, infections) is there a 'free' exchange of antigens between the external and internal environment. Both types of epithelia possess antigen handling (uptake, processing and presentation) systems.

Antigen uptake by the skin

Several types of nonepithelial cells can be found in the skin, such as lymphocytes, macrophages and, in the epidermis, Langerhans cells. Langerhans cells are involved in the processing and presentation of antigens that enter the skin. They form an extensive network in the basal layers of the epidermis and are efficient antigen-processing cells, capable of taking

up exogenous antigens by virtue of several specialized surface receptors. The display of antigenic peptides by major histocompatibility complex (MHC) molecules on the surface of the cell permits presentation to passing T cells. This process can take place in the epidermis, but Langerhans cells can also, under the influence of factors produced in the skin as a result of antigenic stimulation, leave their sentinel position in the basal layers of the epidermis. As shown in kinetic studies using fluoresceinated dyes, they can be found in lymphatic vessels and migrate into the draining lymph nodes. During this migration they show characteristic, extended membrane processes, for which they are termed veiled cells. Once they have arrived in the lymph node they localize in the paracortical areas where, as dendritic, interdigitating cells, they play a pivotal role in the primary activation of T lymphocytes. Thus Langerhans cells, veiled cells and interdigitating cells are different stages of the dendritic cell lineage (Figure 1). While Langerhans cells are extremely efficient at processing antigen, once they arrive in the lymph node they differentiate into potent presenting cells at the expense of their processing capacity. This is reflected in the expression of MHC molecules and accessory molecules, which increase during the differentiation into interdigitating cells.

It is only under pathological conditions that cells in the skin other than Langerhans cells are involved in antigen handling. In such cases keratinocytes can express MHC class II molecules and are able to present antigen. Studies on squamous (mucosal) epithelia have shown that antigen-processing and -presenting dendritic cells also occur in the non-keratinizing epithelia of the oral and nasal mucosa,

Figure 1 Migration of Langerhans cells from the epidermis into the draining lymph node. Antigens are processed in the skin by Langerhans cells, and stimuli produced by keratinocytes induce the cells to migrate to the lymph nodes. Here they differentiate into antigen-presenting dendritic cells. Langerhans cells are replaced by monocyte-derived precursors.

the trachea and bronchi, the esophagus and the tonsils, and can form comparable networks at these sites. In simple epithelial membranes, such as the epithelium lining the lung, the stomach and the gut, there is no proof for the existence of extensive networks of dendritic cells, although solitary dendritic cells have been demonstrated. In these organs other antigen-handling systems are operative (see below).

Antigen uptake by mucosal surfaces

The structure of mucosal surfaces (epithelium with tight junctions and a mucous layer) itself is an important determinant of antigen exclusion. Macromolecules are shown to transgress this barrier by endocytosis. Granulocytes, macrophages and plasma cells in the lamina propria interact with these absorbed antigens, thus forming a secondary barrier of defense against penetration of antigens into the circulation. Certain diseases or altered states (e.g. malnutrition, vitamin A deficiency, decreased gastric acidity, allergy) may allow for increased amounts of macromolecular transport. It is thought, for example, that tight junctional complexes present between the mucosal epithelial cells are broken down during malnutrition and vitamin A deficiency. In

addition to the epithelial barrier, the mucosa contains a high proportion of lymphoid cells, the so-called intraepithelial lymphocytes (IELs). These cells are mainly localized in the basal area of the epithelium and bear either cytotoxic T cell or natural killer cell markers.

In the gastrointestinal and respiratory tracts a specialized antigen transport system exists which allows for the efficient transport of macromolecules from the lumen to the organized gastrointestinal and respiratory tract lymphoid tissue (gut-associated, nose-associated and bronchus-associated lymphoid tissue – GALT, NALT and BALT, respectively). The epithelium covering these lymphoid tissues contains specialized antigen-transporting membranous (M) cells.

Antigen uptake by the gut

The gut is constantly challenged with large doses of soluble and particulate antigens. Although it is highly antigen-impermeable, the gut possesses specialized antigen transport mechanisms in the epithelium covering the Peyer's patches (PPs), the appendix and scattered lymphoid follicles. M cells are commonly interspersed between enterocytes; their numbers vary between species. M cells are physically attached to enterocytes via conventional junctional complexes. Although the intermediate filament composition and glycosylation state of M cells is slightly different from that of the surrounding enterocytes, the junctional complexes and the presence of epithelial-specific vimentin and cytokeratin expression in M cells provide evidence for an epithelial origin of M cells, in contrast to all other types of antigen-handling cells which are bone marrow derived. M cells differ from the rest of the epithelial cells in histochemical and ultrastructural respects. At the microscope level these cells can be recognized by their close association with IELs. M cells possess large basolateral pocked domains which harbour specialized IELs. In ultrathin sections, an M cell is seen as a rim of apical cytoplasm that bridges the space between the adjacent enterocytes (Figure 2). This M cell forms a kind of umbrella above a space in which IELs, and sometimes macrophages and dendritic cells, are present. Antigen is absorbed at the apical side of the M cell; absorption may be aided by the lack of a 'fuzzy coat' and the absence of mucous (goblet) cells in the PP epithelium. Following absorption, antigen is endocytosed and transported into vesicles to the lateral and basal cell membrane; by fusion the antigen is released into the basolateral space, where it comes into contact with lymphocytes and macrophages or dendritic cells. Antigen is transcytosed by M cells

Figure 2 (A) A Peyer's patch; (B) detail of an M cell within the Peyer's patch epithelium. After uptake and transport by the M cell, antigen is processed by macrophages or by dendritic cells which transform into interdigitating cells (IDCs) and is then presented to lymphocytes in the T cell areas of Peyer's patches and mesenteric lymph nodes (MLN). E, enterocyte; L, lymphocyte; m, macrophage/dendritic cell.

with little or no degradation. It is picked up by macrophages or dendritic cells and presented to local lymphocytes or transported to the interfollicular T cell areas of PPs or mesenteric lymph nodes where antigen is presented by interdigitating cells (IDCs). These antigen-presenting IDCs are derived from the dendritic cells that had picked up antigen within the epithelium.

There are indications that antigen uptake by the M cells in the PP epithelium induces a secretory IgA immune response. In addition, a systemic suppression is exerted by the generation of suppressor T cells inside PPs. It is suggested that part of the intestinal antigens – in particular soluble, low molecular weight antigens – are absorbed by the

enterocytes of the villous epithelium. Enterocytes, in particular those of the small intestine, constitutively express MHC class II molecules and it has been shown that these cells are able to present antigen. There are indications that antigen presentation by enterocytes leads to the generation of T suppressor cells which are involved in systemic suppression and tolerance induction. These findings have significant implications in local gut immune responses and may explain the poorly understood phenomena of oral tolerance induction and systemic suppression.

Antigen uptake by the upper and lower respiratory tract

The nasal and oral cavities are covered by a (pseudo)stratified epithelium, that acts, due to surface protection by mucus and sIgA, as an adequate barrier. This epithelium possesses antigen-presenting Langerhans-like (dendritic) cells. Painting of this area with fluoresceinated dyes indicates that dendritic cells can bind antigen and transport it to the draining lymph nodes (in particular the cervical mandibular lymph nodes) for an adequate immune response. The epithelium of the mucosal surface of the oral and upper respiratory tract, except for the epithelium above lymphoid structures (Waldeyer's lymphoid ring), is involved in antigen exclusion rather than in antigen uptake. The epithelium above the ring of Waldeyer – in the nose the lymphoid tissue has been described under the name NALT – contains, just as BALT and GALT do, antigen-transporting M cells

by which the local mucosal immune system is allowed to react adequately.

Antigen-presenting dendritic cells which constitutively express MHC class I and II molecules have also been described in the pseudostratified epithelium of the trachea and the bronchi. The majority of them are localized in the mucosa, either above or below the basement membrane, and in the lamina propria. Although there are no clear data about the migration route of these cells, there are indications that after antigen uptake dendritic cells migrate to the draining lymph nodes for antigen presentation. The lower respiratory tract, in particular the lung, is thought to be involved in antigen exclusion rather than in antigen uptake. Clearance of antigens from this part of the respiratory tract mainly depends on mucociliary activity and alveolar macrophages. The alveolar macrophage population, however, appears to be heterogeneous, both morphologically and functionally. Some macrophages act as real scavenger cells (they phagocytose and digest antigen, and leave the lungs via the mucociliary trap), some are apparently inhibitory, while others display a stimulating effect on the local immune response by presenting antigen to lymphoid cells. Most probably this latter effect is brought about by migration of alveolar macrophages from the alveoli into the lung tissue. It has been shown that antigen-laden alveolar macrophages cross the lining of the alveoli and migrate to and present antigen in the draining lymph node. In this way alveolar macrophages act as dendritic cells forming a specialized antigen handling system in the

lungs. Figure 3 illustrates the interactions between the immune 'compartments' of the lower respiratory tract. Antigens can reach the draining lymph nodes via diverse routes and there are indications that the site where antigen is taken up, processed and presented determines the outcome of the immune response.

ANTIGEN PRESENTATION VIA MHC CLASS I MOLECULES

Emil R Unanue, Department of Pathology and Center for Immunology, Washington University School of Medicine, St Louis, Missouri, USA

As described in Antigen Presentation via MHC Class II molecules, the T cell receptor for antigen, either of the CD4 or CD8 subset, must interact with peptides bound to the major histocompatibility complex (MHC) molecules. Both the class I and II MHC molecules inform the T lymphocytes of the intracellular content of peptides. CD8 T cells interact primarily with peptides bound to class I MHC molecules. As was initially shown, CD8 T cells directed to viruses can be triggered by viral peptides. Two major differences between presentation by the class I and the class II MHC molecules are, first, that the class I molecules serve to select primarily, but not exclusively,

peptides derived from cytoplasmic proteins – the class II molecules select peptides from proteins found in the vesicular system; and, second, that the primary site of coupling of class I molecules with peptides is the endoplasmic reticulum (ER) – the major site of peptide coupling by class II molecules is in vesicles. In this form, the lymphocyte recognizes products from viruses and some bacteria by way of the MHC class I system, and products of intracellular bacteria or parasites (and of endocytosed/phagocytosed antigens) by the class II MHC system. Details on the biology of antigen-presenting cell (APC)–CD8 T cell interaction have been given under Antigen-Presenting Cells.

Cellular events

The interactions of CD8 T cells first involves a recognition of the peptides bound to class I MHC molecules of APC and the activation of the lymphocyte. This interaction is similar in principle to that involving CD4 T cells with APCs bearing class II MHC molecules. The interaction of the naive CD8 T cells involves the presence of adhesion molecules and the activation of the T cells by costimulatory molecules. Once activated, CD8 T cells can kill different types of target cells bearing the peptide–class I MHC complex. It is thought that very few peptide–MHC complexes are needed for recognition and cytolysis by CD8 T cells (i.e. less than a hundred per cell).

The cellular events involved in the presentation of peptides by class I MHC molecules involve four major steps. First is the catabolism of the protein antigen, which takes place in the cytoplasm. Second is the transport of peptides from cytosol to the ER, and third is the assembly of the peptide–MHC complex at that site. The last step is the transport to the cell surface.

That the cytosol is the site of generation of peptides first came from the studies on viral infections where viral peptides were found to be the main target of CD8 T cells. This recognition brought about protective antiviral immunity. Subsequently, proteins were introduced directly into the cytosol of target cells, and peptides derived from them were found to be associated with class I molecules. In contrast to presentation of peptides by class II molecules, presentation by class I molecules was not sensitive to lysosomotropic alkalinizing agents. The latter, however, was inhibited by peptide derivatives that inhibited the proteasome. Tri- or dipeptide aldehydes inhibited proteasome catabolic activity *in vitro* as well as *in vivo* generation of class I bound peptides. The proteasome is a large multicatalytic protein complex composed of multiple subunits that together form a 26S particle (~1500 kDa). The proteasome subunits are uniquely assembled into a large cylindrical structure, that is responsible for the ATP-dependent proteolysis of ubiquitin-conjugated proteins. Proteasome catabolism controls the turnover of a number of important cytosolic proteins, including transcription factors and cell cyclins. Ubiquitin is a small polypeptide that is attached by way of several enzymatic steps to lysine in cytosolic proteins. Ubiquitin marks the protein for proteasomal catabolism. Whether all peptides bound to class I MHC molecules are derived from ubiquitination of proteins is not clear at present. Peptides akin in structure to those generated by APCs have been generated *in vitro*.

Many of the class I bound-peptides are derived from proteasome catabolism. Two of the enzymes

that form the proteasome are, in fact, expressed, particularly after exposure of cells to interferon γ . These two subunits, LMP2 and LMP7, influence the nature of the catabolic process favoring hydrolysis of peptides after hydrophobic or basic residues. Cells that do not express either of these two enzymes show different profiles of presentation of peptides. LMP2 and LMP7 together with the TAP transporters described below are encoded in the MHC gene locus.

Once generated, peptides cross into the lumen of the ER using the TAP molecules (Transporter Associated with antigen Processing). TAP1 and TAP2 are homologous subunits molecules belonging to the family of transporters containing ATP-binding cassettes found in both eukaryotes and prokaryotes. These two membrane-spanning molecules act in concert by binding to cytosolic peptides of a given length, usually 8–12 amino acids, and transporting them into the ER in an ATP-dependent process. The binding of peptides to TAP transporters has been studied using free microsomes or permeabilized cells. Peptides bind to TAP in an ATP-independent process, with μM affinity constants. There is some degree of specificity of peptides–TAP interaction which varies among species and different class I alleles. Interestingly, there is some concordance in peptide preference for TAP transport and that for binding to a class I MHC molecule. The importance of TAP transporters was first brought into attention by cell lines defective in class I MHC expression caused by mutations in TAP molecules. This indicated that TAP molecules were essential for the transport of peptides which is necessary for the assembly of MHC class I–peptide complex.

The site of interaction between class I MHC molecules and peptide occurs in the ER. The formation of a stable trimolecular complex (i.e. heavy chain of class I MHC molecules, β_2 -microglobulin and peptide) takes place following transport of peptides by the TAP molecules. Several steps have been identified in the ER leading to the formation of the peptide–class I complex. Chaperone molecules that normally are found in the ER, such as BiP and calnexin, help in the formation of a correctly folded heavy chain. BiP is a member of the heat shock family of proteins. Calnexin resides like BiP in the ER and participates in the correct folding of many glycoproteins. The heavy chain and the β_2 -microglobulin then associate physically with the TAP molecules. Involved in the final assembly are recently identified helper molecules, such as calreticulin and tapasin, which probably serve to bridge the interaction of the assembled class I molecule with TAP. Calreticulin is a resident ER chaperone molecule of 45 kDa. The precise role of tapasin is yet to be determined. The MHC class I molecules associated

with TAP then establish contact with the recently transported peptides.

Once the MHC-peptide complex is assembled, it is transported to the Golgi and then rapidly to the plasma membrane. Class I MHC molecules devoid of peptide are unstable molecules at physiological temperatures. The fraction of peptide-free MHC molecules that reach the plasma membrane varies depending on the form and species of it.

Class I MHC molecules clearly present peptides derived from the cytosolic catabolism of proteins such as viral proteins or autologous cytosolic proteins. But class I molecules can also be loaded with peptides from proteins that are internalized in vesicles. These include aggregated proteins, proteins from inactivated viruses, bacteria or particulate bound proteins. The pathways that these proteins follow in the cells have been much discussed recently. It may involve transposition of the proteins from vesicles into cytosol, leading to a sequence of events similar to those described above. But an alternative pathway may result in peptides generated in endosomes or lysosomes that in some form become accessible to class I molecules. Regardless of the exact pathway of processing, the point is that proteins taken in by endocytosis/phagocytosis can also lead to peptide loading of class I molecules.

It is noteworthy that viruses have been shown to produce proteins that inhibit presentation by the class I MHC system. This may be one of the ways in which viruses try to evade the immune system. For example, adenovirus E3/19K glycoprotein binds to the class I MHC molecule directly and inhibits its transport to the cell surface. Herpes virus type I ICP47 protein binds to TAP and inhibits transport. Cytomegalovirus also produces proteins that inhibit class I presentation.

Peptide binding

Class I MHC molecules bind to peptides usually of 8 or 9 residues in length. The binding specificity is broad: many different peptides bind to a given class I MHC molecule, although there are clear preferences depending on the peptide sequence, and these vary among class I molecules of a given genotype. Binding of peptides to class I MHC molecules has been studied using purified molecules in solution but most frequently using cells deficient in TAP transporters. These cells have poor basal expression of class I MHC molecules but will increase this expression when cultured with peptides.

In common with the class II molecule, class I molecules do not discriminate between foreign and self peptides. Peptides have been extracted from class I

molecules of different target cells. These peptides were isolated, fractionated, usually by reverse phase high-pressure liquid chromatography, and then sequenced. Class I molecules were found to contain hundreds of peptides, many of them representing autologous cytosolic proteins.

The biochemical basis of peptide binding has been extensively analyzed following the pioneering studies by Bjorkman and colleagues from Wiley and Strominger's laboratories. There are features in common between the structure of the binding site of both class I and II molecules. The binding site is located at the top of the molecule. It contains a cleft or 'groove', the peptide-combining site, which is made by a platform of β -pleated sheet surrounded by two helices. The groove is about 30 Å in length and 12 Å in its center. Amino acid residues responsible for the extensive allelic polymorphism contact the peptides and are responsible for their binding specificity. For class I MHC molecules, both the α_1 and α_2 domains contribute to the combining site. Each domain contributes to half the number of β sheets and one of the helices. The α_3 domain of the heavy chain and β_2 -microglobulin serve to hold and give support to the top two domains.

Peptides are bound to class I molecules as a result of two sets of interaction. One is that of conserved amino acid residues of the class I heavy chain, with amino acids at each end of the peptide. Amino acid residues at the ends of the peptide form extensive hydrogen bonds with conserved residues at subsites located at each end (termed pockets A and F). The peptides bound at each end will run through the groove as an extended conformation. Depending on the particular peptide and class I molecule, the peptide may or may not bulge or kink towards the middle of it. The extensive hydrogen bonding of the main chain atoms of the peptide with the conserved residues of the MHC molecule stabilizes the complex. A second set of interactions takes place with side-chains of the peptide. These side-chain-specific interactions are responsible for the sequence binding motifs that have been identified. Particularly prominent for most class I bound peptides are interactions at the second and last residue.

Some of the residues in the peptide are solvent exposed and will establish contact with the T cell receptor. The X-ray structure of the T cell receptor bound to a class I MHC molecule shows the receptor contacting the α helices of the MHC molecules as well as the peptide. The peptide occupies about the center of the peptide-binding structure available to the T cell. The receptor is oriented slightly diagonal to the main axis of the peptide, with the CDR3 region of their α and β chains contacting the middle

of the peptides and the CDR1 and CDR2 contacting the peptide ends and the MHC. Thus the structural analysis confirms the dual specificity of the T cell receptor for peptide and MHC molecules, as was predicted by the findings of MHC restriction.

ANTIGEN PRESENTATION VIA MHC CLASS II MOLECULES

Emil R Unanue, Department of Pathology and Center for Immunology, Washington University School of Medicine, St Louis, Missouri, USA

During antigen presentation a protein is taken up and processed by antigen presenting cells (APCs), and is then recognized by T lymphocytes. The basic patterns of protein recognition apply to both CD4 and CD8 T lymphocytes. Both cells do not recognize protein antigens in their native state but only after the antigens are taken up by an APC. The role of the APC is to process the protein into denatured fragments or peptides that complex with their class I or II major histocompatibility complex (MHC) molecules. The peptide–MHC bimolecular complex represents the antigenic determinant recognized by the $\alpha\beta$ T cell receptor of CD4 or CD8 T cells. However, there are notable differences between recognition by CD4 or CD8 T cells in that CD4 T cells recognize the peptides associated with class II MHC molecules, while CD8 T lymphocytes recognize the peptides associated with class I molecules. The CD4 or CD8 molecules interact with either the class II or class I molecule, respectively, favoring the interaction of the T cell receptor with the MHC–peptide complex.

Historical background

The early studies on responses to protein antigens established a relationship between the degree of uptake of the antigen by the ‘reticuloendothelial system’ and its immunogenicity. This was most evident

in the responses to foreign albumins or gamma globulins where the antigenic preparations differed in their content of polymeric molecules. Albumin or gamma globulins with a heavy content of polymers (or aggregates) were strongly immunogenic while, in contrast, preparations made mostly of monomers were poorly immunogenic or even tolerogenic. The degree of uptake by spleen macrophages of polymers was much higher than of monomers. That these results could be ascribed to the uptake by macrophages was ascertained in experiments in which macrophages that had taken up the protein were isolated and transferred to syngeneic hosts. The recipients made strong responses to the macrophage-associated antigen. Therefore, the macrophage, a cell responsible for protein catabolism, was linked to the immunogenicity of the antigen.

An understanding of this phenomenon required the introduction of cell culture techniques. In culture, APCs were strictly required for antibody responses, or for responses by T lymphocytes to protein antigen or to plant lectins. The depletion of APCs, usually by their property of adherence to culture dishes, resulted in an absolute lack of T cell proliferation or of cytokine secretion. It was in 1973, through the studies of Shevach and Rosenthal, in the inbred guinea pig strains 2 and 13, that it became apparent that T lymphocytes not only required the presence

of macrophages but of macrophages that were syngeneic. The class II MHC molecules were essential elements in this interaction. Further experiments, also first in the guinea pig, led to the concept of determinant selection: that the T cell recognizes antigenic determinants selected by APCs of a given MHC genotype. Thus, antigen presentation was related to the immune response gene phenomena reported in inbred strains of mice and guinea pigs. The 'immune response' gene experiments and those of MHC restriction and determinant selection set the base for the cellular and molecular understanding of this very early inductive phase of T cell recognition and of antigen presentation.

Antigen processing was first inferred from observations on the specificity of antigenic recognition by B and T cells. B cells usually recognize protein antigens in their native state. Much of the antibodies found in blood after immunization with a globular protein antigen bind to the protein in its three-dimensional conformation and not to the denatured protein. This indicates that the native protein antigen was selected by B cells with specific immunoglobulin (Ig) receptors for it, prior to its unfolding by the host's catabolic processes. In contrast, T cells recognize the denatured protein or fragments of it. This was first ascertained by examining a variety of T cell reactions (delayed hypersensitivity, secretion of cytokines, proliferation). In such examples there was no difference if the protein was presented in its native state, unfolded or as a peptide fragment. These phenomena are now explained by the more recent findings indicating that protein antigens are processed by APCs, that some but not all processed peptides bind to a given allelic form of class II MHC molecules, and that the MHC-peptide complex represents the antigenic determinant that engages the T cell receptor.

Cellular events

Antigen presentation takes place very rapidly upon entry of antigen into lymphoid tissues. Presumably macrophages and Langerhans-dendritic cells take up the antigen and are responsible for the early recruitment and activation of CD4 T cells. B cells that have surface immunoglobulin molecules with specificity for the antigen also participate by binding the antigen, processing it and presenting it to the CD4 T cells.

Antigen presentation comprises other events besides processing of the antigen and formation of the peptide-MHC complex. First, the antigen-specific T cells must establish physical contact with the APCs. Second, T cells require to interact with two sets of molecules provided by APCs: costimulatory

molecules, in order to enter cell cycle and to activate cytokine-specific genes; and cytokines that modulate their expression of different genes. Clearly T cell activation is a multistage process involving a 'signal 1', the engagement of the T cell receptor, and various 'signal 2'. The molecules that primarily promote physical contact are termed cell adhesion molecules (or CAMs), while those that primarily promote growth and differentiation are termed costimulators. Details of the APC-T cell interaction are given in the Antigen-Presenting Cell article which contains a table showing the molecules involved.

The interaction between the APCs and the CD4 T cells is physically manifested by close cell-to-cell contact. This intimate APC-CD4 T cell contact is favored by cell adhesion molecules the lymphocyte functional antigen-1 (LFA-1) on the T cells with its corresponding ligands, ICAM-1, ICAM-2 and ICAM-3 on the APCs; and the CD2 molecule with its counter-receptor. The functional effects of the interaction are reciprocal – macrophages will be stimulated to release cytokines, B cells will proliferate and differentiate, while the CD4 T cells will also proliferate and release cytokines.

Costimulator molecules are key in determining that the engagement of the T cell antigen receptor to the MHC-peptide complex is a productive interaction. These include the B7-1 and B7-2 molecules on APCs (and their coreceptors CD28 and CTLA-4 on T cells), and the CD40 molecule on B cells in particular, and the CD40 ligand coreceptors on T cells. These costimulator molecules may act by inducing early release by T cells of growth factors such as interleukin-2 (IL-2) and/or by regulating the expression of receptors for growth factors, and by inhibiting apoptosis. *In vitro* experiments indicate that exposure of T cells to fixed APCs (which cannot provide costimulatory molecules) results in an absent response. Such T cells, in fact, may develop an unresponsive or anergic state. Costimulatory molecules of APCs are expressed in low amounts. The representation of their expression is one component that initiates productive presentation. Finally to note is that several cytokines from APCs modulate the T cell response during antigen presentation. Included are IL-1 α and β , tumor necrosis factor- α (TNF α), IL-6 and IL-12. This latter cytokine is key in the differentiation of T cells to the T_H1 subset.

Antigen processing

Processing refers biochemically to the unfolding of the proteins and/or the generation of peptides as a result of their partial proteolysis. Globular proteins in their native state do not bind to MHC class II

proteins: proteins are required to have conformational flexibility in order to be able to bind and mold into the combining site of an MHC molecule. This flexibility is brought about either by denaturing the protein or partially fragmenting it to small peptides. The denatured proteins or the peptides, in contrast to the native unfolded molecule, interact and complex to the class II MHC molecules.

Processing by APCs involves several successive stages: 1) the internalization of the antigen into acid intracellular vesicles; 2) its partial proteolysis; 3) its coupling to intracellular MHC II molecules; and 4) its transport to the plasma membrane.

Protein antigens internalized by APCs are taken to deep intracellular vesicles where unfolding of the protein and/or its partial catabolism to peptides then takes place. The denatured protein and/or peptides are thus available to bind to class II MHC molecules. The most recent evidence suggests that this encounter takes place preferentially, but not exclusively, with class II MHC molecules that have been recently synthesized, and that this encounter takes place in vesicles with the properties of early lysosomes.

Class II MHC molecules assemble in the endoplasmic reticulum (ER) and traverse the Golgi vesicles associated with a nonpolymorphic polypeptide, the invariant chain. Invariant chain and the $\alpha\beta$ dimers of class II molecules form a complex that is transported to vesicles outside the Golgi vesicles. The estimate is that a trimerized invariant chain binds to three class II molecules (i.e. three $\alpha\beta$ dimers), thus forming a nonameric complex. The invariant chain has signal sequences in its cytosolic portion that serves to guide the complex out of the Golgi into late vesicles. The invariant chain also has the important property of covering the combining site of the class II molecule during its travel through the ER. Thus, during their sojourn through the ER and Golgi the class II molecules have less opportunity to interact with peptides derived from catabolism of self peptides. The invariant chain has different isoforms that may be involved in different ways in the fate of the complex.

Once the invariant chain- $\alpha\beta$ complex leaves the Golgi, the invariant chain is catabolized in a proteolysis rich, acidic compartment; however, a segment of the invariant chain comprising residues 81–104 remains associated with the combining site. This peptide, termed CLIP, must be removed to make the $\alpha\beta$ dimer competent to bind foreign (or autologous) peptides. A secondary auxiliary molecule (HLA-DM in humans or H2-M in the mouse) then associates with the $\alpha\beta$ dimer containing the CLIP peptide. This association leads to the removal of CLIP. How this protein associates with the $\alpha\beta$ dimer, and the basic

interaction that favors a fast off-rate of the bound peptide still requires analysis. As the CLIP peptide is removed, high-affinity binding peptides found in the vesicular 'loading' compartment then bind. Thus, there is an exchange of peptides, with CLIP leaving, and strong binding peptides occupying, the class II MHC molecule. Class II molecules with bound peptides are then transported to the plasma membrane, the site of interaction with the T cell and its receptor.

Many of the class II MHC bound peptides have a very slow off-rate and, therefore, remain bound during their entire span in the APC. In fact the half-life of the class II MHC molecules reflects their content of different affinity peptides. Some of the class II molecules bearing weak binding peptides can exchange peptides in endosomal vesicles or at the plasma membrane.

Thus, a scenario that is favored is that an internalized protein (i.e. a soluble protein or a microbe containing a large array of proteins) is taken to a deep lysosomal compartment, and it is there that peptides are generated from partial proteolysis. Nascent class II molecules meet with these peptides and an effective peptide exchange reaction takes place, as described above. Peptides that are bound, i.e. 'selected', are protected from further proteolysis. Class II molecules are, therefore, peptide-binding molecules that protect from extensive catabolism. Figure 1 illustrates the antigen-processing events depicted using the protein lysozyme.

The nature of the proteolytic event that results in the degradation of the invariant chain and of the protein antigen is still under much consideration. Most likely, cathepsins are involved in the degradation. A strong case has been made for the involvement of cathepsin S in invariant chain degradation. Concerning the protein antigen, one way of viewing the processing event is to postulate the unfolding of the protein, after which the denatured unfolded polypeptide binds to class II molecules through the segment displaying sequences that favor high binding to MHC molecules. Once bound, the portion of the unfolded peptide that spills out of the peptide-combining site is catabolized, perhaps by amino- and carboxypeptidases, up to the limit of the combining site.

There has been much discussion about the nature of the MHC-peptide loading compartment (called MIIC). An organelle containing lysosomal proteins and class II MHC molecules, and which receives internalized protein late, has been identified by electron microscopy, and also defined by subcellular fractionation. Thus, for many protein antigens this late vesicular and lysosomal-like compartment may be the site of loading to nascent class II molecules. However, it is also clear that peptides can bind class

Figure 1 Processing of the protein hen egg white lysozyme (HEL). There are two functional compartments in APCs, depicted as the two squares: a deep compartment (left) and a recycling or endosomal compartment (right). HEL is a globular protein that requires denaturation by reduction of its four disulfide bonds (dHEL). This takes place after HEL reaches the deep compartment. The dHEL binds to the $\alpha\beta$ dimers of class II MHC, after their exit for ER–Golgi. $\alpha\beta$ dimers exit bound to the invariant chain ($\alpha\beta$ -Ii). The invariant chain is degraded leaving CLIP peptides bound to it. The HLA-DM molecules remove CLIP making the $\alpha\beta$ dimers competent to bind dHEL. The dHEL bound to class II molecules is trimmed by amino- and carboxypeptidases to a peptide of 15–16 residues. The peptide is transported to plasma membrane. The dHEL not bound is catabolized to amino acids (box with dots). If APCs are given HEL already denatured, it can bind to $\alpha\beta$ dimers in endosomes where peptide exchange takes place. Peptides can also bind directly to some peptide-free $\alpha\beta$ dimers at the cell surface.

II molecules in early endosomes or, if available, at the plasma membrane. The nature of the protein, and the ease by which the protein is subjected to denaturation and partial proteolysis, clearly are factors in determining the site of loading. Autologous proteins, which are rapidly secreted from APCs, can also load into class II molecules during their short travel through APCs. This is an indication that there is some degree of proteolysis taking place during secretion and that the loading process is very effective. Lastly, peptides derived from cytosolic molecules have been found bound to class II molecules, an indication that cytoplasmic-derived peptides are also accessible to the class II MHC system. However, whenever a comparison has been made, peptides derived from cytosolic proteins are less effective than those found in vesicular proteins in reaching the class II MHC system.

Binding properties of class II MHC molecules

The binding properties of class II MHC molecules can be studied using purified molecules, usually in

detergent solutions, or directly in the APC. Purified class II molecules bind peptides in a homogeneous saturable process with binding affinity constants in the 10^{-6} – 10^{-8} M range. The rate of association of peptide with the MHC molecule is slow, but once the peptide is bound it can form a very stable and long-lived complex. The complex of MHC with peptide can be assembled and isolated in free solution, and can directly trigger CD4 T cells these experiments have been done with T cell hybridomas that are triggered by the engagement of their receptor without the need of costimulatory molecules. Binding of peptides to class II MHC molecules can also be directly determined on APCs by using peptides tagged with a radioactive or fluorescent label, or with photoreactivatable probes. In live APCs the proportion of class II MHC molecules that need to be occupied by a given peptide to trigger T cells is small, usually about 0.1% of total class II MHC (about 10^{-2} in the APCs studied so far).

The binding of peptides takes place in the antigen-binding site of the MHC molecules, which was defined through structural studies of purified complexes pioneered in the laboratory of Don Wiley and

Jack Strominger. The main architectural features are found for both the combining site of class I and II MHC molecules. For class II molecules the binding site is at the top of the molecule and consists of a groove or pocket made up of a platform of β -pleated sheets, derived from the α_1 and β_1 domains, surrounded by α helices, also made from portions of α_1 and β_1 domains. Most of the amino acid residues responsible for allelic polymorphism, found in the α_1 and β_1 domains, are located in the helices and in the platform. These residues are believed to be involved in interaction (charge or ionic, or hydrophobic) with residues in the processed protein antigen.

Peptides are found in an extended conformation with a slight twist typical of polyproline II-like conformations. Two types of interaction determine the affinity and specificity of peptide binding: those between the peptide backbone and conserved residues of the MHC molecules; and those between side-chains of critical amino acids with sites of the MHC molecule. The first set of interactions include hydrogen bonds between the conserved residues in the MHC molecules and the peptide backbone. This extensive array of hydrogen bonds contributes to the affinity of the peptide and is dependent on the length of the peptides. In contrast, side-chains of amino acids interacting with critical areas in the combining site give specificity to the interaction. The sites or areas have preference for different amino acids side-chains. The amino acid residues of the MHC pockets characterize a given MHC genotype.

Binding kinetics and competition experiments indicate the single peptide-binding site can be occupied by peptides of 8–30 amino acid residues. The specificity of peptide binding is broad, assuring that many different peptide structures can be recognized by the T cell system. Several peptide motifs that favor binding to class II MHC molecules have been identified. Not all of these motifs so far identified predict all T cell determinants. A peptide contains amino acid residues that contact the MHC binding site and other residues that contact the T cell receptor. The contact residues for MHC and T cell receptors are intermingled in the peptide. Usually 1–3 residues are solvent exposed and serve primarily to contact the T cell receptor. To note is that although there is broad binding specificity, not all peptides bind to a given allelic form of an MHC class II protein. The weak binding, or lack of it, results, as expected, in very poor activation of the specific T cells. It is the weak or poor binding of peptides to a given allelic variant of class II MHC molecules that explains many of the immune response gene effects described from early studies on inbred mice.

An important observation first made with lysozyme peptides is that the class II MHC binding site does not discriminate between self and nonself peptides. Self peptides have been shown to bind or not to bind, depending on their structural features. Hence, self and nonself peptides behave in the same way insofar as their binding properties to a given class II protein. Moreover, it has now been shown that APCs isolated from different tissues, including the thymus, contain self peptides associated with them. Indeed, the number of different self peptides isolated from class II molecules is in the hundreds. Some peptides derive from uptake of extracellular molecules but the majority derive from membrane proteins of the vesicular system.

The binding of self peptides to MHC molecules results in three potentially important effects: 1) on the thymus stromal cells it may be instrumental in causing the death or negative selection of maturing T cells; 2) on APCs of peripheral lymphoid tissues, self peptides may compete for the binding of foreign peptides to MHC class II molecules; and 3) such MHC-peptide complexes on APCs can potentially trigger autoreactive T cells, to cause autoimmunity. Of course, reactivity to foreign or self antigens comprises multiple steps and factors of which the generation of the MHC-peptide complex is only one.

ANTIGENIC VARIATION

Antigenic variation is a well-established mechanism among infectious organisms for escaping the immune response of the host. It is a Darwinian process in which alteration of the antigenicity of surface molecules enables infectious organisms to escape immune elimination. These alterations are the result of random mutations, and organisms that acquire surface changes that allow them to escape from host recognition will have a selective advantage and predominate. Antigenic variation is the principal means of persistence of protozoans such as African trypanosomes, *Plasmodium* spp., *Giardia* and several species of bacteria, including *Neisseria gonorrhoeae* and *Borrelia* spp., in an infected individual. This phenomenon also allows for the persistence of animal viruses. The classic example of antigenic variation of viruses is observed among the influenza A viruses. Influenza viruses do not establish persistent infections in individuals, but alterations in the surface glycoproteins as the virus spreads through a population allow for reinfection of individuals and therefore the persistence of influenza viruses in a population and worldwide.

Antigenic variation of viruses within an individual host occurs with the lentiviruses. Lentiviruses include the human immunodeficiency virus (HIV) and an increasing number of animal viruses which cause persistent infections with chronic disease. Antigenic variation has also been observed for the enteroviruses (poliovirus, Coxsackie virus, echoviruses) and for the common cold viruses (rhinovirus types 22 and 51). Even monotypic viruses, such as measles, exhibit genetic diversity in surface proteins. More detailed descriptions of the molecular mechanisms of antigenic variation of trypanosomes (an example of protozoans), influenza A viruses and lentiviruses are provided here.

Differential gene expression in trypanosomes results in antigenic variation

Trypanosomes are eukaryotic flagellates that cause sleeping sickness in humans and nagana in cattle. These protozoan parasites are transmitted by insects to the bloodstream of the host. The trypanosome has a number of developmental stages. The bloodstream-stage trypanosomes are covered with a dense coat composed of a single type of glycoprotein, the vari-

ant surface glycoprotein (VSG). Antigenic variation in trypanosomes occurs through the sequential expression of different VSG genes. During the course of infection, trypanosomes with serologically unrelated coats are periodically generated, thus allowing evasion of the humoral immune response produced against previously circulating coat VSG.

Each trypanosome has a large repertoire of different VSG genes (100–1000, depending on the species). The switch from one coat to another occurs at a low frequency (10^{-6} or 10^{-7} per cell division) and appears to be independent of immune selection. Only a single VSG gene is usually expressed at one time. The active VSG gene is invariably in a telomeric location in a VSG expression site. Although there are multiple expression sites, located on a few specific chromosomes, only one site is active at any given time. Nonexpressed or silent VSG genes are clustered at internal positions on the chromosomes and are also found at many of the chromosome telomeres. Activation of specific VSG genes occurs by two genetic mechanisms. The first is gene replacement, by duplicative transposition of a new VSG gene into a transcriptionally active expression site. This is thought to occur via homologous recombination. Selection of VSG genes is dictated by the degree of homology between two loci, which may explain the loosely defined order of appearance of trypanosome variants during an infection. The second mechanism for activation of VSG genes is the activation of an alternative expression site. The promoters of expression sites are negatively controlled, and transcriptional activation is thought to be mutually exclusive. Transcription of VSG genes is insensitive to α -amanitin, but the polymerase involved is not known. There is evidence that the presence of an unusual DNA base, pdJ, may be involved in the inactivation of expression sites.

Despite the enormous VSG gene pool available, the reproduction of variant antigenic types is limited in the trypanosome: this prevents the exhaustion of the surface glycoprotein repertoire at an early stage of disease. Antigenic variation also occurs in trypanosome surface receptors involved in food uptake. These variants are limited in number, making these proteins a better target for vaccine development. The bacterium *Borrelia hermsii*, which causes relapsing fever, uses DNA rearrangement

mechanisms for producing antigenic variants similar to those seen with trypanosomes.

Antigenic 'shift' and 'drift' in the influenza viruses

Among the influenza A viruses, both of the surface glycoproteins (the hemagglutinin and neuraminidase) undergo two types of variation: antigenic drift and antigenic shift. Antigenic drift involves minor changes in the antigenicity of the surface protein and is thought to be responsible for the persistence of the virus in a susceptible population. Antigenic shift involves major genetic changes that are responsible for the development of the 'new' viruses in the host species. Antibodies to the hemagglutinin neutralize the infectivity of the virus, and variation in this protein is mainly responsible for recurring outbreaks of influenza and for the failure to produce an effective vaccine. Extremely high concentrations of antibodies to the neuraminidase can also neutralize the infectivity of influenza viruses. This neutralization may occur by a saturation of antibody-binding sites on the neuraminidase resulting in steric inhibition of the hemagglutinin.

Antigenic drift of either surface molecule occurs by the accumulation of point mutations in the respective gene; however, single point mutations appear to have little effect on the antigenic properties of the proteins. Nucleotide sequence analyses of epidemiologically significant strains suggest that single amino acid changes in two or more epitopes of the hemagglutinin are necessary for a significant antigenic change. The most likely mechanism for mutations in multiple epitopes is single mutations occurring sequentially during the spread of the virus from person to person. Strains with single mutations in one epitope must escape the immunity of an individual, possibly because the humoral immune response in humans is heterogeneous and the limited antibody repertoire against influenza virus in children probably permits such selection.

Antigenic shift involves replacement of at least the hemagglutinin gene via genetic exchange with an avian or animal virus. The new shift variant can cause a pandemic, as no neutralizing antibodies are present in the human population. There is evidence for genetic reassortment between human and animal influenza viruses *in vivo*. A shift virus which emerged in 1968 contained a human neuraminidase gene, but the hemagglutinin was 98% homologous at the nucleotide level with an avian influenza A virus. It is believed that new pandemic strains are produced by co-infection of pigs with avian and human influenza virus strains.

Antigenic variation in lentiviruses

Antigenic variation in an individual host occurs with animal lentiviruses. The first report of antigenic drift was in equine infectious anemia virus (EIAV). Horses infected with EIAV develop sequential episodes of acute hemolytic crises during persistent infections. Sera taken at various times from an infected animal were able to neutralize isolates from previous clinical episodes, but failed to neutralize subsequent viral isolates. Visna virus in sheep also causes persistent infection, although episodic disease is not observed. Like EIAV, antigenic variants of visna virus emerge over time in persistently infected sheep. This antigenic drift can be duplicated in cell culture using plaque-purified virus and monospecific antibody for the selection of variants.

The molecular mechanism of antigenic variation in the lentiviruses is the accumulation of single nucleotide changes in the surface glycoprotein genes. In visna virus the accumulation of point mutations appears to be progressive. Antigenic variant viruses sequentially isolated from a single animal contained the same point mutations when compared to the input virus. Antibodies produced by the animal to a particular variant recognized all changes found in the other preceding variants, supporting the cumulative and progressive nature of antigenic drift in visna virus.

In both visna virus and EIAV, point mutations are seen throughout the surface glycoprotein gene, but hypervariable regions have been identified. Antigenic variation in visna virus can be detected 1 year after infection and continues throughout the infection. In contrast, antigenic drift in EIAV occurs more rapidly, in the first weeks after infection, and continues until the host develops a broad antibody response against the virus. Distinct EIAV variants can be associated with each clinical episode. However, unlike visna virus, no accumulation of point mutations has been observed; variation is more random.

Extensive genetic heterogeneity of HIV isolates from infected individuals has also been observed, and may provide evidence for antigenic drift *in vivo*. Genetically diverse viruses, or 'quasispecies', are produced in infected individuals due to the infidelity of the viral reverse transcriptase. Recent studies have shown that the evolutionary dynamics displayed by these heterogeneous virus populations *in vivo* is consistent with adaptive evolution. Also, antigenic variants of HIV have been isolated in cell culture using a molecularly cloned virus and sera from an immune individual. Host neutralizing antibodies appear to be at least one of the selective pressures responsible for the emergence of antigenic variants. However, other

selective forces, such as cell-mediated immune responses, may also play a role in the production of variants. The role of these antigenically-distinct viruses in the pathogenesis of HIV is unclear.

Antigenic variation and immunity

Antigenic variation of protozoans, bacteria and animal viruses provides a mechanism for persistence of the organism in its host, but makes immunological control difficult. The strategy used for the development of influenza A virus vaccines has been to identify the circulating strains early in the influenza season and to rapidly produce a vaccine against the predominant strains. In lentiviruses this strategy cannot be used because mutation and selection occur in a single infected host. Thus a wide repertoire of neutralizing epitopes must be included in a vaccine to prevent the evolution of lentiviruses that can evade the host immune response.

ANTIGENS

Michael Sela, Department of Chemical Immunology, The Weizmann Institute of Science, Rehovot, Israel

Antigen is any substance (molecule) that provokes the production of specific antibody or immunocyte (immune cell), or that interacts specifically with these products of the immune response, when penetrating the body of a vertebrate. The first part of this definition, namely, the capacity to provoke an immune response is also called immunogenicity and the substance provoking such a response is called immunogen. The second part, the specific interaction, is called antigenic specificity. A chemical or physical

change in a molecule that will result in an increased immune response will increase its immunogenicity, even though it may or may not change its antigenic specificity. It is the antigenic determinant (also called epitope) which is responsible for the specificity.

The ability to mount an immune response depends ultimately upon the interplay between the chemistry of the antigen and the physiologic state of the host. Thus, immunogenicity is operationally dependent on the experimental conditions of the system, including

parameters such as the antigen, the mode of immunization, the organism being immunized and its genetic background, as well as the sensitivity of methods used to detect a response.

It is worth stressing that we are using the word antigen sometimes for a molecule, sometimes for a virus or a bacterium, and sometimes for an organ or a tissue, but the antibodies have a *combining site* (also defined as *paratope*), with all its distinctive features, of a more or less similar size and cavity. These combining sites are not complementary to a complete bacterium or a complete heart, but they are always complementary to a unique antigenic determinant which is of a limited molecular size.

Among the immunocytes we recognize B cells (the precursors of antibody-producing cells) and T cells. The combining sites on B cells are essentially the same as those of the antibodies which their progeny will produce. On the other hand, the combining sites of the T cell receptors are distinct from those of antibodies. What is characteristic of the T cell receptors is that they recognize generally the antigen after it has been processed within a cell and presented to the T cell receptor in conjunction with either class I or class II antigens. These are antigens defined by immune response genes which are part of the major histocompatibility complex (MHC). Most antigens are thymus dependent, which means that they need to be recognized in the above manner. A minority of antigens, called thymus independent, do not need the recognition by T cells, and may lead to efficient antibody formation after interacting exclusively with B cells.

The notion of antigen includes also the capacity to induce specific immunological tolerance, or anergy, defined as a state of T lymphocyte unresponsiveness characterized by the absence of proliferation (human T cell clonal anergy).

The recognition of antigens by the T cell compartment of the immune system is a multistep process culminating in the formation of a ternary complex between the T cell receptor for antigen (TCR) and the binary complex of class I or II MHC encoded molecules, with short peptides derived from the antigen. Thus, the specificity of the TCR is for a *neoantigen* determinant composed of both, the genetically restricting MHC molecule and the bound peptide. The recognition process may therefore be considered as consisting of two distinct phases, the first in which peptides are produced and get bound to the MHC encoded proteins, and the second where the TCR binds this binary complex. Since MHC encoded molecules may bind peptides derived from both self and nonself proteins, the fundamental implication of the above is the need for a selection process where cells

with TCR that bind self-peptides are eliminated during the development process in the thymus, yielding a repertoire of mature T cells that recognize MHC complexes with nonself peptides.

The antigenic determinants leading to the formation of antibodies by B cells may be parts of proteins, nucleic acids, polysaccharides, lipids or glycolipids, or other biological macromolecules. Very often they have unique steric conformations and are part of a native structure. We have thus to distinguish between sequential determinants (epitopes) and conformation-dependent (or conformational) determinants (epitopes). The operational definition holds that if antibodies against, e.g. a protein, react well with a tetra-, penta- or hexapeptide derived from that protein, then the antibody is against a sequential determinant. The antibody, on the other hand, is against a conformation-dependent determinant if it is made against a juxtaposition of atoms in space which results from a unique conformation of the macromolecule, and any peptide derived from such a protein will not be able, after denaturation, to react with the antibody.

It is of interest that for most globular proteins and native nucleic acids, almost all the antigenic determinants are conformation dependent, whereas for most polysaccharides, fibrillar proteins such as silk fibroin, and single-stranded nucleic acids, the determinants are sequential. The use of homopolymers of amino acids or sugars, and of peptidyl proteins as antigens has established that the sequential determinant is composed of 4–6 amino acid or sugar residues which contribute unequally to binding with the antibody combining site.

Not all the antigenic determinants express themselves all the time: some are more immunopotent than others. Some do not express themselves at all under a certain set of conditions, and we call them immunosilent, even though under other conditions they may provoke an efficient immune response. Thus a determinant may be immunosilent within a complete macromolecule, but may be quite immunopotent when a segment of that macromolecule on which it is present is used for immunization. Situations are also known where a determinant is immunosilent but becomes immunopotent in animals made tolerant to other parts of the immunogenic macromolecule of which the determinant discussed forms a part. We may thus define immunopotency as the capacity of a region of an antigen molecule to serve as an antigenic determinant and induce the formation of a specific immune response.

The term hapten, in its strictest sense, designates any substance, large or small, which does not elicit an immune response by itself but can be shown to

react with antibody provoked by immunization with a complete immunogen of which the hapten formed a part. In practice, most haptens investigated are small chemical substances, in most cases of a size definitely smaller than that of a complete antigenic determinant. When attached to a protein, haptens such as dinitrophenyl or penicilloyl might be defined as immunodominant parts of an antigenic determinant (an epitope). In studies of determinants of polysaccharide or polypeptide nature, it is of interest to establish which is their immunodominant portion.

Generally an organism distinguishes between self (material which is its own) and nonself (any foreign material). The immune system of an organism reacts against any foreign compound (antigen), and is tolerant (unable to react) towards its own body components, which may be good immunogens in other organisms. This self-tolerance is acquired during fetal or neonatal development, and the immune system can be made tolerant even to foreign material or tissue introduced during this period. Such material, which can induce immunological tolerance or unresponsiveness, is called a tolerogen.

Another phenomenon which should be mentioned here is antigenic competition. This may occur between different antigens (intermolecular), or between different specificity determinants on the same antigen (intramolecular), in which case we define it as competition between antigenic determinants. The existence of this phenomenon may account for some determinants being immunosilent under certain circumstances. Antigenic competition may be defined as the inhibition of the immune response to one antigen or determinant by the administration of another antigen or determinant.

Molecules as antigens

The two types of natural macromolecules most investigated as antigens are proteins and polysaccharides. These also include glycoproteins, nucleoproteins, lipoproteins, etc., as well as peptidoglycans, glycolipids and other conjugates. Nucleic acids are also antigenic. Lipids are poor immunogens, but antibodies against them can be obtained, and liposomes play a role here, as they do in enhancing the immunogenicity of various other antigens. Synthetic antigens, especially synthetic polypeptides, have played an important role in the elucidation of the molecular basis of antigenicity and many other immunological phenomena, and they will be discussed here in more detail below. Other synthetic polymers have also been shown to be immunogenic, e.g. polyvinylpyrrolidone.

All proteins are probably immunogenic, although

individual proteins differ markedly in their immunogenicities. Denatured proteins are often less immunogenic than the corresponding native proteins. Self-aggregation of a protein is usually associated with a negligible change in its antigenic specificity, but with a considerable increase in immunogenicity. Like other antigens, proteins possess a continuous spectrum of antigenic determinants that correspond to discrete portions of the surface structure and that are preferentially located in those regions most exposed to the external environment. The relationship between structure and antigenicity is, however, more complex for globular proteins than for other antigens, in that it depends to a very large extent upon the overall conformation of the molecule. The exploration of antigenic regions on the surface of proteins has become easier with the advent of monoclonal antibodies and rapid methods of peptide synthesis. The antigenic sites may be described as surface domains made up from amino acid side chains which may be distant in sequence but close in space (conformation-dependent determinants). Such domains are probably overlapping and cover most of the protein surface. On the other hand, fibrous proteins possess sequential determinants, of three to six amino acid residues.

Special attention has been paid by immunologists to those proteins which possess distinct and easy-to-measure biological properties. These include enzymes and enzyme inhibitors, protein hormones, toxins, antibodies (i.e. immunoglobulins as antigens), as well as proteins composing viral coats. Immunologic studies have also been successful in following the evolution of proteins.

The other class of substances that was readily shown to be antigenic comprises the polysaccharides. Although complex, they nevertheless provide antigens of relatively simple structure by which many of the detailed structural aspects of antigenic determinants and antibody combining sites have been worked out. Microbial polysaccharides are located on the cell surface and are, therefore, of importance in recognition and immune responses of a higher organism to microbial infection. The simplest polysaccharide antigens are dextran, a polymer composed entirely of glucose, and levan, composed entirely of fructose. Another important group contains the capsular polysaccharides of pneumococci. Complex lipopolysaccharide antigens, endotoxins, are found in a large variety of microorganisms, notably in gram-negative Enterobacteriaceae, such as *Salmonella* and *Shigella*. The polysaccharide determinants are predominantly sequential, consisting usually of 4–6 sugars, but some antibodies may have combining sites which are smaller.

Blood group antigens are the other important category of polysaccharide antigens. They are gene-dependent structures expressing the individuality of cell surfaces, body fluids and secretions. Chemical characterization of blood group structures has been fully developed. The chemical structures of ABH and Lewis antigens have been elucidated using water-soluble blood group substances isolated from secretions (ovarian cyst mucin, gastric mucin). These structures, when on erythrocytes and other cells, are part of more complete glycolipid or glycoprotein antigens.

Antigenic functions of nucleic acids were only recognized much later than those of proteins or polysaccharides. No immunogen has yet been prepared that would be capable of inducing in experimental animals antibodies to double-stranded DNA. Such antibodies are, nevertheless, available in humans suffering from systemic lupus erythematosus, as well as in mice and dogs with similar diseases. Their sera usually also contain antibodies to single-stranded, denatured DNA, as well as to RNA, double-stranded RNA, histone and nucleoprotein. It is possible to induce antibodies to single-stranded RNA or DNA, either by immunizing these, complexed with a macromolecule of opposite electrical charge, or by preparing conjugates of nucleosides, nucleotides or oligonucleotides, with proteins or synthetic polypeptide antigens, and using them as immunogens. Complex formation of methylated bovine serum albumin with synthetic polynucleotides, including some that were double-stranded and triple-stranded, yielded a mosaic of antigens, some of which recognized the higher order structure of these macromolecules.

Progress in the field of lipid immunology is more recent, and largely due to advances in lipid and membrane chemistry. This led to a heightened awareness of lipids as important cellular antigens. Among the lipids, most important immunologically are phosphatides, such as sphingomyelin and cephalin, as well as glycosphingolipids such as galactocerebroside. Antibodies against lipoidal extracts of various tissues appear during the course of syphilitic infection, and this led to a standard serological test for syphilis. Another lipid antigen is the Forssman antigen, mainly responsible for hemolysis of sheep erythrocytes in the presence of antiserum and complement. The greatest barriers to advancement in the field of lipid immunology have always been the chemical and physical properties of the lipids themselves, particularly water insolubility. The problem of reactivity of soluble antibodies with lipid antigens was partially overcome by the inclusion of 'auxiliary lipids' such as lecithin and cholesterol in the antigen

suspension. Mixtures of lipids in the form of liposomes, consisting of concentric spherules of lipid bilayer membranes, can mimic precisely many of the immunological aspects of intact cell membranes. The availability of liposomes has permitted the study of the immunogenicity of membrane-associated lipids.

Immunoglobulins

Immunoglobulins (Igs) are mentioned here exclusively in terms of their antigenicity. Usually immunological data preceded structural information, and they were crucial, e.g. in the discovery of allotype and idiotypy. The availability of monoclonal antibodies permits today a detailed antigenic analysis of immunoglobulins of every class and type. The epitopes within one immunoglobulin molecule vary much in their relative immunopotencies. Thus some determinants on the Fc fragment of an IgG are immunodominant compared with determinants on Fab, but when Fab is injected, in the absence of Fc, either by itself or as the dimer (Fab)₂, antibodies are produced efficiently against epitopes on the Fab fragment of IgG.

Antigenic analysis helped not only to distinguish between the various classes (IgG, IgM, IgA, IgE, IgD) and subclasses of immunoglobulins, but also to define their phylogeny. Allotypes are immunologically detectable genetic differences in particular constant regions, whereas idiotypes are the unique antigenic determinants found on the variable regions of antigen binding receptors, i.e. they represent paratopes of different specificities (idiotypes) in terms of their antigen variation. The regulation of the immune system through idiotypic-anti-idiotypic interactions can be achieved without the presence of the antigen, and, thus, is particularly well suited to the maintenance of steady states in lymphoid populations after the antigenic stimulus has been removed. Indeed, idiotypic-anti-idiotypic relationships have the potential to link diverse members of the immune system into a network, so that the activation of one set of clones within the system may have far-reaching and quite unanticipated effects elsewhere within the 'immunological network'.

Synthetic antigens

Landsteiner first showed that small molecules (e.g. 2,4-dinitrophenol) when injected into animals do not elicit antigen formation. However, dinitrophenyl proteins, in which dinitrophenyl is attached to a macromolecular carrier, elicit the formation of antibodies reacting specifically with the dinitrophenyl group. Such small molecules were termed haptens.

Thus a new antigenic specificity may be grafted on an antigen. On the other hand, a limited enrichment of gelatin with tyrosine increased its immunogenicity without significantly changing its specificity. Thus by chemical modification it is possible to change both immunogenicity and antigenic specificity. Increase in immunogenicity by means of appropriate adjuvants has developed significantly due to synthetic adjuvants which may also be attached covalently to the antigen.

Synthetic polypeptides (polymers of amino acids), linear and branched, have been used extensively in immunological research, as their structures were both simple and well known. This permitted the construction of literally hundreds of antigens for the purpose of elucidating the molecular basis of antigenicity, and later the molecular basis of manifold immunological phenomena.

Knowing the chemistry of the copolymers made it possible to arrive at conclusions concerning the role of various structural features in their antigenic function. It is, nevertheless, important to stress that the immunogenicity of a chemical substance depends not only on its structure but also on the biological background of the animal immunized, including its genetic features. It was thus learned that the immunogenically important area of the molecule must be readily accessible to the B cell and cannot be hidden in the interior of the molecule. By chemical modification, antigenic materials may be converted into nonantigens (e.g. by attachment of poly(ethylene glycol) or by poly(DL-alanylation)), whereas nonantigenic materials may become immunogenic.

The overall shape of the molecule does not seem to be a crucial factor in immunogenicity, whereas the size seems to be important: very few molecules of less than 2000 Da are immunogenic, and the immunogenicity increases steadily with the molecular size. The presence of electrical charges on a macromolecule is not a minimum requirement for it to be immunogenic.

Appropriately constructed polymers of D-amino acids may be immunogenic in a similar way to polymers of the natural L-amino acids, but to detect this antigenicity, it is necessary to immunize animals with very low doses, as in the dose range required to prove the immunogenicity of L-amino acid polymers, the D-polymers induce immunological tolerance, also called paralysis. This is probably due to their being very slowly, if at all, metabolized. Through studies of structurally related immunogens, it was possible to establish that those antigens, such as pneumococcal polysaccharides, *Escherichia coli* lipopolysaccharides or D-amino acid polymers, which possess repeating antigenic determinants and are slowly

metabolized, are T independent, i.e. they do not need the cooperation of the helper T cells with B cells, whose progeny produce antibodies, for an efficient immune response. In contrast, most antigens – including L-amino acid copolymers – are T dependent. The purely cellular immune response is limited to the T cell population, of which several subpopulations are now known, and it probably involves the cooperation of helper T cells with effector T cells.

Antigens leading to an immune response of essentially any specificity desired can be prepared synthetically, and this includes the production of antibodies against peptides, oligosaccharides, oligonucleotides, tRNA, lipids, as well as haptens such as penicillin, prostaglandin, dinitrophenol, pyridoxal or ferrocene. Similarly, antibodies have been obtained against many biologically active peptides such as angiotensin, bradykinin or vasopressin. Moreover, in recent years totally synthetic immunogens, including peptide segments of viral coat proteins, e.g. MS2 bacteriophage, hepatitis virus or bacterial toxins (diphtheria, cholera) have been produced, and they have led to the production of antibodies capable of neutralizing the virus, or inducing in experimental animals protection against diphtheria and cholera.

The spatial folding of proteins plays a decisive role in determining their antigenic specificity. With synthetic models, it has been possible to build with the same peptides, immunogens which possessed either exclusively sequential or conformation-dependent antigenic determinants. In globular proteins, most of the antigenic determinants are conformational, as is evident by loss of reaction with their antibodies after denaturation. Antibodies are, therefore, good probes for the conformational state of proteins, and there are many reported cases in which antibodies have been used for detection of different conformations in proteins. Working from these considerations, we have shown that a peptide analogous to a stretch of the hen eggwhite lysozyme sequence can be synthesized, closed into a 'loop' by a disulfide bridge and attached to a synthetic branched polymer. The resulting macromolecule leads to production of antibodies which cross-react efficiently with a unique conformation-dependent region of a native protein. In conceptual terms this opened the road to the synthetic vaccines of the future as it pinpointed the possibility of synthetically preparing relevant determinants that could lead to protection against diseases.

To give just one of the many examples where synthetic antigens were of crucial importance in detecting, or elucidating, a defined immunological phenomenon, the genetic control of immune response should be mentioned. It is clear today that

the capacity to respond well or poorly to a certain antigenic stimulus is under strict genetic control. This observation has been made largely thanks to synthetic antigens (simple chemically) and inbred strains of animals (simple genetically). Using defined branched synthetic polypeptides, differing only in a limited manner within their antigenic determinants, it was possible to prove conclusively that the genetic control of the immune response is determinant specific. McDevitt showed later that the immune response to these synthetic antigens was linked to the MHC locus of the species. The newly discovered immune response (Ir) genes and their products (Ia) have been extremely important in enabling us to understand the phenomena of immunity and resistance to diseases. The Ir gene products (Ia antigens) are present on the cell surface and are important in controlling interactions between cells of the immune system.

Complex antigens

Antigens of importance in practical immunology are mostly not dispersed molecules but cellular or multicellular structures. Of course, the specificity is ultimately definable in all cases in molecular terms. Viruses, sometimes even crystallizable, are among the simplest of such structures, with most of the antigenic specificity residing in their coats, sometimes of purely protein nature, but often including lipids or polysaccharides. In some cases, inner core proteins are also efficient antigens, capable of providing a protective immune response. More has been learned about immunology from studies on bacteria than from any other group of natural antigens, and their antigenic determinants have been in many cases elucidated in great detail, most of it of a polysaccharide nature, but also involving proteins and teichoic acids. Lipids often participate in these specificities. More limited progress has been made in the investigation of mycoplasmas and chlamydiae. On the other hand, recent years have seen a tremendous progress in the immunology of parasite diseases, due to both helminths and protozoa, including the great antigenic variations characteristic of some agents. Fungi are another group of antigens that express an enormous number of antigenically different entities, about whose molecular nature relatively little is known.

Vaccines used in medical practice include four main types of antigen preparations: toxoids (the soluble exotoxins of bacteria such as diphtheria and tetanus bacilli, which have been modified and rendered less toxic by the addition of formalin or gentle heating); antigens isolated from infectious

agents (such as the capsular polysaccharide of the pneumococci); killed vaccines (cultured organisms killed by heat, ultraviolet irradiation or chemicals such as phenol, alcohol or formalin); and attenuated living vaccines (made from strains of organisms that have lost their virulence by growth in culture).

Allergens are antigens which cause allergic reactions either of the immediate or delayed type. They may be of widely different origins such as dust, fungi, hair, pollen, bacterial proteins, food or drugs. The immediate-type allergy is induced mainly through a mechanism triggered by IgE class antibodies, whereas the delayed-type allergy is T cell mediated.

All plant and animal cells possess antigens that can express themselves in a foreign host. Many animal and human antigens may trigger autoimmune phenomena. Some antigens may be organ specific, whereas others are present essentially on all cells (e.g. histocompatibility antigens). In the past two decades the central role of the MHC in immune processes has been recognized. The MHC, a cluster of diverse genes which mediate and regulate a variety of immune mechanisms, appears to exist in all higher vertebrate species (HLA in humans; H2 in mice). Genetic, structural and functional studies of the multiple MHC products have defined three broad classes of genes and molecules. The class I products are glycoproteins expressed on the membranes of all nucleated cells (histocompatibility, or transplantation, antigens). These are the main targets of the graft rejection reaction, and they mediate the recognition and destruction of virus-infected or neoplastic cells. Class II products, defined by immune response (Ir) genes, are expressed principally on the membranes of antigen-presenting cells (e.g. macrophages, dendritic cells, B lymphocytes) and mediate the regulation, through so-called helper and suppressor effects, of a variety of humoral and cellular immune responses. When incompatible, these Ir gene products also play a potentiating role in transplant rejections. Class III genes determine the structures of several discrete proteins including certain components of the complement system which cause destruction and elimination of bacteria and other foreign cells.

No listing of natural antigens would be complete without mentioning all the cellular markers, receptors and tissue antigens. There is a growing number of immunologically and chemically defined antigens characteristic of various types of T cells, and also B cells and macrophages. There are also all the cytokines, molecules provoked in cells and secreted into body fluids, such as interleukins, interferons, thymic and tumor factors, etc.

There are many indications that the cancer patient's immune response may affect tumor growth.

In the study of tumor immunity, the identification of new tumor-specific antigens not present in normal tissues is a primary task. One has to distinguish them from organ-specific antigens and histocompatibility antigens. Tumor antigens are often tumor selective rather than tumor specific, i.e. their concentration may be much higher on cancer cells than on normal cells. Tumor antigens are classified according to the origin of the tumor: experimentally induced (by chemical, physical or viral carcinogens) or spontaneous. The category of oncodevelopmental antigens is of special interest. These, exemplified by α -fetoprotein and by the carcinoembryonic antigen of the colon, are present in normal individuals before birth but disappear thereafter (or stay at an extremely low level), and reappear in the body fluids in adult life only concurrently with specific cancers. Their quantification may, therefore, be of diagnostic value. Antitumor antibodies may be used for immunotargeting of toxins (immunotoxins) and chemotherapeutic drugs.

ANTIGENS, CELL SURFACE

Wolfgang J Rettig, Dr Karl Thomae GmbH, Germany

The basic structure of the plasma membrane is a lipid bilayer with intercalated proteins and carbohydrate side-chains extending from the external membrane surface. Chemical studies with SDS-polyacrylamide gel electrophoresis, lectin chromatography and glycolipid analysis have shown that plasma mem-

branes isolated from various tissues differ widely in their protein and carbohydrate composition. However, by far the most detailed picture of plasma membrane diversity, especially with regard to the diversity displayed on the external membrane surface, has come from immunologic studies.

Immunogenetic classification of cell surface diversity

Four genetically distinct categories of cell surface diversity have been identified with serologic and cell-mediated immune reactions (Table 1). First, the discovery of the human ABO blood group antigens and mouse H-2 major histocompatibility antigens established precedents for allogeneic diversity. Allogeneic diversity is specified by genetic polymorphism, i.e. the presence and mendelian inheritance of different alleles of a common gene in members of the same species. The allelic variation may reside in 1) the structural gene for a cell surface protein, as illustrated by major histocompatibility complex (MHC) class I and class II molecules; 2) the activity of an enzyme involved in carbohydrate synthesis, as illustrated by blood group antigens; or 3) a regulatory gene or DNA sequence controlling the expression of a structural gene, as suggested for the TL antigens of TL⁺ and TL⁻ mouse strains.

Second, xenogeneic diversity reflects genotypic differences between members of different species and includes instances in which homologous cell surface molecules in disparate species show structural diversity (e.g. mouse versus human Thy 1) and instances in which an antigen in one species has no apparent structural homolog in another species (e.g. apparent lack of genes homologous to mouse Tla in several other species). A special case of xenogeneic diversity detected on the plasma membrane of mammalian cells is antigens encoded by viral genes integrated into the host cell genome. Despite the clear genetic distinction, the observed patterns of viral antigen expression may be deceptively complex, as illustrated by the murine leukemia virus (MuLV)-encoded gp70 cell surface antigens of mouse leukemias. MuLV genetic information is ubiquitous in the mouse, but whether these endogenous viral genes are expressed or not is determined by a variety of viral and host

gene functions. For example, the expression of specific gp70 determinants differs between mouse strains with low and high leukemia incidence and between differentiated normal tissues in the same animal, thus mimicking the distribution of alloantigens or restricted differentiation antigens encoded by host genes. Apart from direct insertion of viral proteins into the plasma membrane, peptides generated from the intracellular degradation of viral proteins may bind to MHC molecules and be presented on the cell surface, where they can be recognized by T cells.

Third, clonogenetic diversity is determined by somatic genetic changes in gene structure, such as mutations and recombinational events. Genetic recombination is a normal step in immunoglobulin (Ig) and T cell receptor (TCR) gene expression, whereas mutations due to hits by external mutagens or errors in replication may affect any surface antigen gene in somatic cells. Such changes will escape notice unless an affected cell undergoes clonal expansion. For example, malignant transformation of individual B cell or T cell clones has allowed serologic detection of clonotypic determinants on surface Igs and TCRs. The individually distinct tumor rejection antigens of chemically induced sarcomas of mice, the unique antigens of human melanoma detected by autologous typing, and the tum⁻ antigens of mutagenized mouse tumors may represent clonogenetic diversity of this sort on nonlymphoid cells. In the case of unique antigens of human melanoma, the serologic specificity has been traced to a variant of a normal melanocyte surface antigen, melanotransferrin. In the case of tum⁻ antigens, the mutations affect genes encoding for intracellular rather than cell surface components, and the clonotypic determinants appear to reside on endogenous peptides that are presented on the cell surface by MHC molecules and recognized by T cells.

The fourth category of cell surface diversity can

Table 1 Immunogenetic classification of cell surface antigen diversity

<i>Designation</i>	<i>Genetic basis</i>	<i>Prototype antigens</i>	<i>Reagents (examples)</i>
Allogeneic	Allelic differences	MHC class I, II antigens Blood groups	Alloantisera mAbs T cell clones
Xenogeneic	Species divergence for homologous genes Endogenous viral genes	Most surface proteins Virus-coded tumor antigens	Heteroantibodies Heteroantibodies
Clonogenetic	Gene recombination Somatic mutations	TCR; Igs Unique tumor antigens	mAbs Autologous antibodies T cell clones
Epigenetic	Regulated expression	CD antigens	mAbs Heteroantibodies

be referred to as epigenetic ('differentiation-related') diversity and reflects differences in gene expression, rather than disparity of gene structure. (In this context, the term differentiation can be used for all processes that lead to diversity in the patterns of proteins synthesized in cells harboring the same genome, such as embryonic and fetal development, normal self-renewal and terminal differentiation in adult tissues, inflammation, tissue repair and malignant transformation.) Prior to the impact of serologic analysis, there was a general notion coming from transplantation studies with tolerant and chimeric animals that cells from different lineages shared a common surface antigenic phenotype. The first examples of cell surface antigens that distinguish different cell types in the same animal were discovered some 25 years ago in the search for tumor-specific antigens of mouse leukemias. At that time, H-2 was the only known cell surface antigen on these tumor cells. However, specific immunization and testing schemes devised to obviate anti-H-2 responses, led to the detection of several new antigenic systems, including TL, Thy-1, Lyt-1 and Lyt-2,3. Like H-2, these antigens were found both on leukemic cells, which in the mouse are commonly of T cell origin and arise in the thymus, and on normal thymocytes. Unlike H-2, the newly defined antigens showed a restricted distribution among other lymphoid cells and in non-lymphoid tissues and came to be known as differentiation antigens. Enormous interest was generated by the finding that specific cell surface phenotypes not only permitted a distinction between T and B cells, but also between T cell subsets with cytotoxic (Lyt-2,3⁺) and helper cell (Lyt-2,3⁻) activities. This gave rise to the now widely accepted idea that the surface of cells reflects their differentiated state and that cells undergoing distinct pathways of differentiation or serving disparate functions have unique surface phenotypes.

The terms used here to classify cell surface diversity apply to the epitopes defined by specific antibodies or T cells rather than to entire molecules. Any individual cell surface molecule, be it a differentiation antigen or not, may combine structural features that are xenogeneic, allogeneic and clonogenic in nature.

Test systems and approaches to cell surface antigen characterization (Table 2)

Initial interest in cell surface antigens came from studies of blood group antigens, histocompatibility antigens and tumor rejection antigens and their role in blood transfusion, organ transplantation and

tumor immunity. The discovery of differentiation antigens established cell surface serology as a new approach to studying general aspects of cellular differentiation, first in cells of hematopoietic origin and subsequently in other cell lineages. With recent developments in serologic, biochemical and genetic techniques and test systems, the study of cell surface differentiation has been vastly expanded and it is now possible to carry out a comprehensive survey of tissue-specific cell surface antigen display. First, hybridoma technology permits sampling of common and rare immune responses and permits rapid analysis of large numbers of monoclonal antibodies (mAbs) without the elaborate specificity controls required for complex hetero- and xenoantisera. Thus, over the past years, mAbs have been used to define hundreds of new cell surface antigens, primarily in humans and mice. Second, indirect immunofluorescence staining combined with cytofluorometry and cell sorting and other techniques allow detailed analysis of hematopoietic cells and other tissues that can be prepared as free-cell suspensions. Cytofluorometry does not lend itself to the analysis of intact tissues. To test substrate-adherent cultured cells, procedures such as radiobinding assays or immunocytochemistry are available. For solid tissues, highly sensitive immunohistochemical procedures have been developed, including indirect immunofluorescence, avidin-biotin complex immunoperoxidase, and alkaline phosphatase (ALP)-anti-ALP procedures. These largely replace absorption assays and other methods that do not permit antigen localization to specific cell types or subcellular structures within tissues. Third, a large number of human and rodent tumor cell lines have been established, representing a wide range of distinct cellular lineages, and much progress has been made in culturing differentiated normal cells. They are used as standard typing panels for antigen specificity and as a source of homogeneous cell populations for biochemical and genetic studies. Fourth, the development of sensitive immunochemical techniques in conjunction with mAbs has led to the definition of a host of plasma membrane proteins, glycolipids and carbohydrates and it has permitted their chemical characterization. For a host of proteins, this analysis has yielded information on their primary structure and facilitated the cloning of antigen-coding cDNAs. In addition, it has allowed distinct cell surface proteins to be placed into families with shared structural features and possibly, common evolutionary ancestry, as exemplified by the immunoglobulin superfamily. Some cell surface antigen genes show alternative mRNA splicing to generate transmembrane, glycosylphosphatidylinositol

Table 2 General approach to cell surface antigen classification

<i>Antigen characteristics</i>	<i>Examples and methodologies</i>
Cell-type specificity	
Cultured cells	Binding assays with short-term cultures of normal cells and tumor cell lines (cotyping)
Tissues	Immunohistochemistry; immunofluorescence staining and flow cytometry (cell suspensions)
Biochemistry	
Proteins	Immunochemistry (immunoprecipitation, Western blotting, purification, amino acid sequencing) Biosynthesis and subunit composition Membrane anchoring
Glycolipids	Carbohydrate and lipid analysis (immuno-thin layer chromatography)
Carbohydrates	Sugar analysis, carrier analysis (lipids, proteins)
Epitope structure	Competition studies with multiple mAbs (radiobinding assay, surface plasmon resonance) Species comparison Molecular structure (amino acid sequence, carbohydrate determinants, conformation-dependence, combinatorial epitope for multimeric antigens) Active site mapping for biochemical functions
Membrane dynamics	
Internalization	Coated pits, caveolae, macropinosomes Surface recycling and processing/degradation of internalized antigen
Extracellular release	Secretion of splice variants lacking membrane anchors Proteolytic release of membrane-bound forms
Genetics	
Molecular cloning	cDNA cloning, sequence analysis for homologies (gene families) and functional domains Alternative mRNA splicing
Gene locus	Chromosome mapping Exon-intron structure, regulatory elements, species comparison Disease-related mutations, deletions and polymorphisms
Biochemical function	Signaling receptors or ligands (cell-bound versus soluble forms) Adhesion molecules Membrane-bound enzymes
Biological function	Growth, differentiation of cultured cells Transgenic animals, knockout animals Altered structure or regulation during development, physiologic activation, or in diseased tissues (inflammation, cancer, immunologic diseases)

(GPI)-linked, and secreted forms of the antigen, or antigens that differ in the length of their cytoplasmic or extracellular domains. Examples of antigens that show this sort of isoform diversity include the neural cell adhesion molecule (NCAM) and the leukocyte common antigen (CD45). Additional diversity within antigenic systems may result from cell type-specific patterns of glycosylation or from differences in subunit assembly in the plasma membrane, as illustrated by the combinatorial diversity of T cell antigen receptor complexes or integrin heterodimers. Analysis of this level of structural diversity is greatly facilitated by the availability of mAbs specific for individual subunits or isoforms carrying shared and unique epitopes. Finally, chromosome mapping and genetic linkage studies that employ 1) serologic analysis of somatic cell hybrids, 2) cytogenetic analysis of inbred and congenic animals, 3) cytogenetic analysis with DNA probes (in situ hybridization to somatic and meiotic chromosomes), and 4) physical mapping with yeast artificial chromosomes and other large

DNA fragments have permitted the construction of genomic maps for cell surface antigen genes.

The plasma membrane is a dynamic structure, with extensive lateral diffusion of surface antigens in the lipid bilayer. Nevertheless, many membrane antigens are not evenly distributed over the entire cell surface (Figure 1). Thus, the paradigm of a 'fluid mosaic' of cell surface molecules freely diffusing within the plane of the plasma membrane has been modified. Complex assemblies of multiple cell membrane components that appear to be organized into specialized cell surface domains have been identified, some of which are anchored to intracellular structures via cytoskeletal proteins. Spatial restriction of cell surface molecules has been documented in detail for polarized epithelial cells and vascular endothelial cells, in which many antigens show preferential localization either to the apical (luminal) surface or to the basolateral surface membranes. Other antigens are targeted to sites of cell-cell or cell-extracellular matrix contacts, to membrane protrusions of invad-

ing cells (invadopodia), or to the leading or trailing edges of migrating cells.

Cell surface antigens are not strictly confined to the outer surface of cells. Instead, they are taken up into intact cells by one of several modes of vesicular internalization (Figure 2). The best-studied uptake mechanism is via clathrin-coated pits and vesicles, a pathway utilized, for example, by the receptors for epidermal growth factor and transferrin. Additional pathways of internalization use caveolae, as shown for the membrane-bound folate-binding protein (FBP) and other GPI-linked surface molecules, or macropinosomes, as shown for the A33 colon cancer antigen. Viruses exploit a number of internalizing cell surface antigens as receptors to gain access to the cell interior, with human immunodeficiency virus (HIV) binding to CD4 being one example. Finally, the clear distinction between surface-bound antigens and secreted antigens has been abandoned because genes encoding *bona fide* integral membrane antigens may also encode soluble antigens found in the extracellular space, either as a result of alternative splicing of membrane-anchoring, transmembrane domains or due to cleavage of the extracellular domains of the membrane-bound forms by specific proteases. These principles apply to a number of cell surface receptors for cytokines that are also found as soluble cytokine-binding proteins and for cytokines that are derived from membrane-bound precursors.

With the new techniques and test systems, the following questions can now be addressed.

1. What is the size of the surface antigen repertoire expressed on normal cells?
2. Which surface molecules are constitutively expressed on all cell types and which are differentially expressed?
3. Of the differentiation antigens, how many follow a single lineage or phase pattern and how many show complex patterns?
4. How is the biochemical function of a cell surface antigen correlated with its cell type specificity?
5. Are the repertoires of cell surface antigens conserved in different species, and are structural homologs expressed with the same tissue specificity and serve the same functions?
6. What is the hierarchy of intrinsic and extrinsic factors that control cell surface differentiation and the coordinate expression of multiple antigenic systems?
7. What is the significance of quantitative variations in the expression of individual antigens on different cell types?
8. Do the various antigens that make up the cell surface have preferential locations as part of a

prescribed organization of surface elements, and what information is encoded by such supramolecular associations?

9. Which alterations in surface phenotype are associated with malignant transformation and other perturbations in normal cell growth and function?

Emerging view of cell surface differentiation

The wealth of information coming from serologic studies of cell surface antigen expression in different species and in diverse cell and tissue types has led to the demise of earlier concepts about how the surface of cells is constructed. Chief among these is the notion that developmental cell lineage patterns provide the general organizing principles for differentiation-related cell surface diversity. The expectation was that distinct cell lineages in developing embryonic and fetal tissues and in self-renewing adult tissues would be marked by unique surface antigens (e.g. lymphoid or neuroectodermal lineage markers) and that discrete phases in these lineages would be marked by differential expression of additional antigens (phase markers). These molecules would serve cell functions unique to the respective lineages and phases and provide convenient histogenetic markers for the study of embryonic development, tumor classification and other cell type analyses. One early exception to this concept was the mouse Thy-1 antigen, which was found not only on thymocytes and peripheral T cells but also on fibroblasts, in brain tissue, and on a few additional cell types. Thus, Thy-1 shows the restricted expression of a differentiation antigen, yet its tissue distribution is complex, overlapping several distinct embryological lineages and showing differences in developmental regulation within these lineages. Subsequent studies have shown that lineage-restricted antigens are the exception and antigens like Thy-1, whose distribution does not conform to embryonic derivation or lineage are the ones commonly found. The reluctance of differentiation antigens to fit into established cell lineage patterns means that comprehensive maps of antigen distribution are required before conclusions can be reached with regard to cell type, tissue type or disease-related specificity.

Apart from normal differentiation antigens, tumor cell surface antigens have been the subject of much research, and the question of their normal tissue distribution has been of key importance. One suggestion has been that tumors re-express molecular and biological traits of fetal cells that are absent from normal adult cells. This theory has not held up for

(A) General cell surface distribution**(B)** Restricted cell surface distribution**(C)** Cell surface shift of cryptic antigens

Figure 1 Differential localization of cell surface antigens. Examples of antigen expression on lymphoid, epithelial and fibroblastic cells are illustrated as follows. (A) Uniform antigen distribution on the surface membrane, as seen for MHC class I molecules. (B) Spatially restricted cell surface distribution on polarized cells growing on extracellular matrix (ECM). In epithelial cells, apical, basolateral and cell junctional patterns are distinguished. For fibroblastic cells, antigen localization to focal adhesion contacts and the leading (or trailing) edge of migrating cells are indicated. (C) Cryptic antigens may be present in intracellular compartments of some cells but become exposed on the surface of other cells. The example shown here represents a mAb-defined carbohydrate structure, lacto-*N*-tetraose (type I blood group precursor), carried by glycolipids and glycoconjugates, that is detectable in the Golgi apparatus of normal adult cells, but becomes further glycosylated and 'cryptic' before reaching the cell surface. By contrast, in fetal endoderm and teratocarcinomas, the glycosylation of lacto-*N*-tetraose moieties is deficient and large numbers of the precursor structure reach the cell surface.

Figure 2 Dynamic view of cell surface antigen expression on the plasma membrane. Using immunocytochemical staining methods with permeabilized cells, some antigens are detected as biosynthetic precursors in the cytoplasm and Golgi complex, prior to their appearance on the cell surface. Similarly, antigens that are internalized through clathrin-coated vesicles, macropinosomes, or caveolae can be followed by these methods until they are either degraded (e.g. lysosomal pathway) or recycled in intact form to the cell surface. Alternative splicing of antigen-coding mRNAs with removal of membrane-anchoring transmembrane domains or cleavage of membrane-bound antigens by specific proteases may result in secreted or shed variants of the antigen.

most cancer antigens when the analysis of normal adult tissues has been sufficiently detailed. Antigens that fit an 'oncofetal' pattern in one system are invariably found in other systems with a different mode of expression and control. Similar departures from the presumed modes of expression have been found for other categories of 'transformation-related' or 'proliferation-related' antigens of cancer cells. (Much of the current interest in tumor-specific antigens focuses on clonogenetic determinants on cell surface differentiation antigens detected by the host immune system, as described above.) Even for those antigens for which a biochemical function has been identified, such as various cell surface receptors, membrane-bound enzymes and adhesion molecules, the unpredictable cross-lineage patterns are observed.

Understanding the genetic and biochemical control of the complexity in cell surface antigen display will require decoding the signals that initiate, regulate and maintain the differentiated state. Understanding

the physiologic role of a cell surface antigen in the organism, even if it has been assigned an *in vitro* biochemical function and its mode of genetic control is known, may require highly specialized test systems. A search for genetic diseases caused by abnormalities in a single cell surface antigen locus may facilitate the study of physiologic function for some molecules, as illustrated by the analysis of patients with leukocyte adhesion deficiency due to defects in the CD18 gene. However, it is tempting to speculate that many common biological functions of the cell surface are not assigned to individual proteins. They are the responsibility of integrated circuits comprising multiple components, both in the plasma membrane and inside and outside of the cell, in which individual proteins serve as structural and functional modules. The same module may be used over and over in different cell types and different circuits to serve different functions, and similar functions may be mediated, in parallel or alternatively, by separate molecular mechanisms. Such a concept is consistent

with the experience that targeted inactivation of genes in knockout mice is commonly associated with unexpectedly subtle phenotypes.

What lessons can be drawn at this stage of the analysis?

1. From the large pool of genes coding for cell surface antigens, distinct but widely overlapping sets are activated during differentiation in disparate lineages.
2. The distinctive surface phenotype of differentiated cells is achieved not by the display of unique lineage-restricted antigens but rather through unique combinations of antigens that are drawn from a common pool.
3. Although the surface phenotype of differentiated cells is quite stable, there is considerable flexibility in reprogramming individual antigens. Surface antigens are not irreversibly silenced or expressed during differentiation but can be induced or suppressed by specific extrinsic/intrinsic signals.
4. Individual surface antigens can be viewed as modular elements that together generate complex and unique surface patterns. This concept of modularity in the construction of cell surfaces could explain unique functions achievable with common elements, as the same module in different cell types would come under different

regulatory control and could impart different information.

ANTIGENS, T DEPENDENT AND INDEPENDENT

Rudolf H Zubler, Division of Hematology, Department of Medicine, University Hospital, Geneva, Switzerland

Defense mechanisms against microbial invaders form a spectrum ranging from relatively primitive innate immunity to highly sophisticated acquired immune responses. The innate immunity uses only invariant, germ line-encoded receptors for the recognition of foreign substances. The T cell-dependent B cell response, on the other hand, produces somatically mutated, high-affinity antibodies with an enormous range of specificities and a variety of constant regions for different effector functions. The B cell response to T-independent antigens occupies an intermediate position in this scheme; it generates essentially low-affinity antibodies of the immunoglobulin M (IgM) class with germ line specificities. The elaboration of high-affinity antibodies by somatic mutation carries

the risk of creating dangerous self-reactive antibodies; the B lymphocytes must be controlled by helper T lymphocytes via 'cognate' T–B interaction (linked recognition of T and B epitopes of the same antigen). Most natural proteins are T-dependent antigens, and B cells can not respond to such antigens without costimulatory signals from cognate T help. T-independent antigens bypass the requirement for cognate T help. They do this by reacting with both B cell antigen receptors and receptors of innate immunity (on B cells or accessory cells) which provide other costimulatory signals. Typical T-independent antigens are microbial sugars, lipid structures and certain nucleic acids which can not be presented to T cells on major histocompatibility

complex (MHC) molecules for linked recognition and must be handled otherwise. Type 1 T-independent antigens (such as endotoxin, lipopolysaccharide) are directly mitogenic for B cells of certain species, while type 2 antigens (e.g. polysaccharides) activate B cells in conjunction with accessory cells, cytokines and other factors, such as complement. However, the T-independent antibody responses, compared to those benefiting from cognate T help, are limited with regard to affinity, isotype pattern and immunologic memory.

Role of costimulatory signals

The immune system should discriminate between self and nonself. It copes with this problem at different levels. Immature lymphocytes which react with self antigens undergo apoptotic cell death, but not all self antigens are present in the lymphopoietic micro-environments. Therefore, the cellular activation processes during immune responses depend on the cotriggering of lymphocytes by different signals, via the antigen receptor and other receptors; triggering at the antigen receptor only, leads to apoptosis or tolerance. Usually, microorganisms or their products generate costimulatory signals for T cells at the level of the antigen-presenting cells. In the case of B cells responding to T-dependent antigens, the critical costimulatory signals are then provided by helper T cells. In particular, the functions of B cells, 1) to generate high-affinity antibodies by somatic mutation (with the risk of producing novel self-reactive antibodies), 2) to switch from IgM to other immunoglobulin isotypes, and 3) to extensively proliferate and generate a memory cell population in addition to antibody secreting cells – depend on cognate T help and take place in the germinal centers of secondary lymphoid organs. However, cognate T–B interaction only occurs if the antigen, after recognition via a B cell epitope, and then internalization and processing by the B cell, produces a T cell epitope (a short peptide) which can then be presented as a complex with an MHC class II molecule on the surface of the B cell. The most important costimulatory signal during cognate T–B interaction is mediated by CD40 ligand (CD40L) on the T cell binding to CD40 on the B cell. CD40 knockout mice generate no germinal center responses and only respond to T-independent antigens. Humans with nonfunctional CD40L mutations suffer from the X-linked hyper IgM syndrome: the germinal center response is lacking and the immune system is overstimulated by T-independent bacterial antigens.

T-independent antigens can provide other costimulatory signals for B cells, directly or via

accessory cells (Figure 1). On the other hand, obligatory T-independent antigens do not induce a germinal center response and, consequently, do not induce either somatic hypermutation or memory. Only certain isotype switches occur (see below).

Type 1 T-independent antigens

Type 1 antigens are directly mitogenic for B cells from certain species. LPS (lipopolysaccharide, endotoxin) of gram-negative bacteria is the prototypic type 1 antigen for murine B cells. CD14, a 55 kDa glycosylphosphatidylinositol (GPI)-anchored glycoprotein, is the major cell surface receptor for the activating effects of LPS on macrophages, B cells and various other cells. Serum lipid transfer protein or LPS-binding protein (LBP) accelerates the transfer of LPS to CD14 in a catalytic fashion. LPS then probably exerts its mitogenic activity by incorporating itself into the cell membrane. Because the lipid A/core portion of LPS bears structural resemblance to the second messenger ceramide, LPS could interact with ceramide-activated protein kinases. However, while LPS is a potent activator of human macrophages, it is not directly mitogenic for human B cells; it acts like a type 2 antigen for human B cells. For murine B cells, one can distinguish between the polyclonal B cell activator function of LPS, which occurs at a high LPS concentration, and the proper type 1 antigen function which occurs at a 1000-fold lower concentration. At the low dose, B cells with the appropriate antigen receptors have the advantage of focusing the mitogen on to themselves; the response, e.g. to DNP-haptenated LPS, then occurs only in hapten-specific B cells.

CD14 functions as a 'pattern recognition receptor' for a range of microbial constituents from gram-negative as well as gram-positive bacteria which, like LPS, activate macrophages. The B cell mitogenic properties of these substances are not yet well characterized. On the other hand, LPS reacts with a variety of receptors, including the CD11b/CD18 integrin, the animal lectin galectin-3 (expressed by activated macrophages) and others. *In vivo*, cytokines, inflammatory mediators and cell adhesion/cell interaction molecules from various accessory cells (macrophages, dendritic cells, natural killer (NK) cells, mast cells, activated bystander T cells, etc.) can participate in a T-independent antigen type 1 response. *In vitro*, high concentrations of appropriate cytokines induce all types of immunoglobulin class switches in LPS-activated B cells.

Figure 1 T-dependent and -independent B cell activation: properties of type 1 and type 2 T-independent antigens compared to T-dependent antigens.

Type 2 T-independent antigens

Although the presence of repeating B cell epitopes, leading to extensive cross-linking of B cell antigen receptors, is a common feature of type 2 antigens, they are not by themselves mitogenic for B cells. They bypass cognate T help only by synergy with the soluble factors and/or cell interaction molecules from accessory cells like those mentioned above; their effects on the B cell antigen receptor and on nonantigen receptors are equally important. Polysaccharides from encapsulated bacteria are the prototypic type 2 antigens in nature.

Effects of type 2 antigens on the B cell antigen receptor

Type 2 antigens are high molecular weight substances with many repeating B epitopes; they can be sugars (dextran, inulin), proteins (polymerized flagellin, viral capsids) or synthetic polymers (polyacrylamide). The number of identical epitopes is an important variable for B cell activation. Monovalent antigens simply occupy the antigen receptors. Bivalent/low-multivalent antigens can be internalized and their T cell epitopes presented to helper T cells. Cognate T help is required for these antigens, to which most natural proteins belong. Too extensively multivalent antigens can inactivate B cells. However,

somewhere in between, multivalent antigens optimally sensitize B cells to various T-independent costimulatory signals. Cross-linking of surface Ig leads to intracellular clustering of protein kinases, phosphatases and other receptor-associated proteins. The outcome depends on the extent of cross-linking and additional variables, such as the rigidity of the antigen backbone, allosteric effects on individual antigen receptors, and persistence of the interaction; type 2 antigens usually have a poor biodegradability.

Historically, type 2 antigens were defined as antigens which produce no antibody response in those mice which later turned out to have the xid defect (X chromosome-linked immunodeficiency). Interestingly, whereas humans with X-linked agammaglobulinemia, caused by mutations of the tyrosine kinase Btk, have a profound B cell maturation defect, the xid mice, with another Btk mutation, only show a defect of B cell activation by type 2 antigens. The signaling defect after Ig cross-linking is irrelevant for the response to T-dependent antigens in these mice.

Effects of type 2 antigens on nonantigen receptors

Polysaccharides are activators of the alternative pathway of the complement system. Via bound complement fragment C3d, they can react with the complement receptor 2, CD21 (the Epstein-Barr

virus receptor on human B cells). CD21 is associated in the B cell membrane with the CD19 signal transduction complex, and thus can generate an activating signal. In addition, B cells, macrophages and other cells express carbohydrate receptors of various kinds/specificities: C-type lectins (selectins, collectins) and others (e.g. galectins). These animal lectins play a role in cell adhesion, phagocytosis and cell activation as well as in interactions of cells with glycosylated serum proteins. In addition, they can recognize carbohydrates on microbial antigens, and thus probably participate in T-independent polysaccharide-specific antibody responses (e.g. the B cell signaling molecules CD23 and CD72 have C-type lectin domains. More generally, the 'adjuvant effect' of type 2 antigens is their capacity to activate accessory cells and induce cytokine secretion by such cells (phagocytes, inflammatory cells, etc.). In principle, activated bystander T cells can also participate in type 2 antigen-dependent B cell activation via cytokines. Moreover, activated B cells themselves are now known to produce a variety of cytokines, including typical 'T cell cytokines' like interleukin 2 (IL-2).

Immunodeficiencies for type 2 antigens

Neonatal mammals generate antibody responses to type 2 antigens either not at all or weakly; human infants under 2 years old respond very poorly to polysaccharides. Thus, some maturation of B cells and/or accessory cells (microenvironments) is necessary. Poor antipolysaccharide responses also occur in common variable immunodeficiencies and in the Wiskott-Aldrich syndrome. In the latter, a mutation in the WASP gene prevents correct expression of a whole series of cell surface molecules. In normal adults, antipolysaccharide responses are greatly compromised after splenectomy. Splenic B cells are important, particularly marginal zone B cells and CD5⁺ B cells. Some investigators consider that CD5⁺ (also called B1) B cells belong to a separate B cell lineage which preferentially expresses certain germ line-encoded (low-affinity, polyreactive) antibody specificities. Alternatively, since CD5 is an (early, pregerminal center) activation marker for B cells, one could conceive that conventional B cells expressing certain (i.e. polyreactive) antigen receptor specificities would be frequently activated *in vivo*. In any case, antipolysaccharide responses, in accordance with their generation outside germinal centers, typically produce only germline antibody specificities, are oligoclonal and primarily restricted to IgM. But isotype switching to IgG2 in humans and IgG3 in mice does occur; interferon γ (IFN γ), IL-3 and granulocyte-macrophage colony-stimulating factor

(GM-CSF) synergistically induce the IgG3 switch in murine B cells exposed to polysaccharides. Conjugate vaccines of polysaccharides linked to proteins induce cognate T-B interaction. Their utilization to enhance defense against encapsulated bacteria in infants and splenectomized or otherwise immunocompromised adults is of medical importance.

Immunogenicity of microbial DNA

dG polynucleotides can form four stranded conformations which are recognized by the scavenger receptor of macrophages. Moreover, certain palindromic DNA motifs, with sequences rarely present in mammalian DNA, can activate macrophages as well as be directly mitogenic for B cells. The mitogenic effect occurs via interaction with presently unknown intracellular receptors following internalization. The presence of an unmethylated CpG core in the active motifs seems to be relevant to self-nonself discrimination; the CpG content is higher in bacteria than in mammalian DNA and cytosine is not methylated in bacteria. The possibility (still theoretical) exists that bacterial surface molecules could be converted into T-independent antigens by complex formation with a mitogenic DNA motif.

B cell superantigens

Other microbial substances act as superantigens by binding to the B cell antigen receptors outside the antigen binding site. *Staphylococcus aureus*-derived protein A is the prototype for this interaction at the B cell level. Polymerized protein A induces strong B cell proliferation and Ig secretion in conjunction with cytokines such as IL-2. Superantigens are polyclonal activators but, rather than stimulating protective immunity, they could deviate the B cell response away from important antigens in the interest of the microorganism.

ANTISERUM

Yasmin Thanavala, Department of Molecular Immunology, Roswell Park Cancer Institute, Buffalo, New York, USA

An antiserum is simply a serum obtained from an immunized animal or vaccinated human. Immunization is the process of introducing an antigen, often repeatedly, and via a variety of routes (intraperitoneal, subcutaneous, intramuscular, intravenous or oral) into an experimental animal. An immunogen is a molecule which is recognized by the immune system and is capable of inducing an immune reaction. The immune response elicited usually consists of a humoral component and a cellular component. The term antibody was coined to designate the serum proteins that are responsible for humoral immunity. Antibodies are synthesized by plasma cells (terminally differentiated B cells) and can be detected in the serum. Thus a serum that contains a greater than usual concentration of antibodies to a particular antigen, usually as a result of immunization (although natural infection can also generate convalescent antisera), is an antiserum against that antigen. Serology is the term classically used to refer to the study of reactions between an antigen and its antiserum.

The antibody response

Initial immunization of an animal results in a slowly rising, limited response consisting mainly of immunoglobulin M (IgM) class antibodies in the serum. Further injections of antigen boost the antibody level, resulting in a long-lasting enhanced response. This secondary response is composed primarily of IgG class antibodies. Antibodies that comprise the secondary response possess a higher affinity for antigen and hence most sera are collected after the onset of a secondary response.

Passive transfer of immunity

Specific immunity can also be conferred upon an animal or human by the passive transfer of antiserum from a specifically immunized donor. The recipient of such an adoptively transferred antiserum becomes immune to the particular antigen, without ever having been directly exposed to the antigen or having responded to the antigen itself. The immunity thus acquired is of short duration and no memory cells are generated. This approach is useful for conferring immunity rapidly, without the time delay needed to generate an active immune response. The main disadvantage of passive immunization was first observed by a physician named Clemens von Pirquet who reported on a phenomenon we now call serum sickness. He observed that patients repeatedly treated by passive immunization with horse serum, containing antibodies to diphtheria toxin, developed fever, skin rashes and joint pains.

Specificity, titer and affinity

Several parameters have to be evaluated to establish the quality and usefulness of an antiserum. These are specificity, titer and affinity.

The most outstanding feature of a good antiserum is specificity. Most antigens express a large number of epitopes and, against each of these, different antibodies may be elicited. A highly specific antiserum is one that reacts only with epitopes on the antigen used to raise it and not to other antigens that resemble it. In practice an antiserum reacts with antigens that in one way or another resemble the immunizing antigen. Extensive absorption against these

cross-reacting antigens will yield a monospecific antiserum.

A high titer antiserum is one which has a large number of antibodies that are specific for the antigen being tested. The titer of an antiserum is generally expressed as the reciprocal of the highest dilution that reacts with antigen to a predetermined end-point in a given assay system.

The affinity of an antibody reflects the strength of binding between a single antibody-combining site (paratope) and an antigenic determinant (epitope). The term avidity is thus used to describe the overall strength of binding between the antigen and antibody. Avidity is influenced by the intrinsic affinity of the antibody for an epitope on its antigen and the valency of both the antibody and the antigen. As a rule, when an antibody and antigen can form multivalent complexes, the overall strength of the interaction (avidity) is greatly increased.

Making antigens immunogenic

There is no perfect recipe for the generation of a good antiserum. Many foreign molecules (viruses, bacteria and cells) elicit strong antibody responses but some foreign substances fail to induce a good antiserum. In some of these instances the immune system can be manipulated to generate a response, and this can be achieved either by modifying the antigen or varying the host animal. Many of these modifications have been established empirically over the years; however, our increased understanding of the molecular events controlling an immune response should allow more rational approaches for the generation of high titer, specific antisera. Before attempting to produce an antiserum, consideration should be given to the following points: the nature of the antigen and its purity, the site/route of immunization, the dose of the antigen, the choice of adjuvants and the genetic background of the animal to be immunized.

In general, particulate antigens and higher molecular weight proteins tend to be more immunogenic than soluble antigens and proteins of low molecular weight. Converting small soluble molecules into large aggregates is an effective way of enhancing their immunogenicity. The physical coupling of a small molecule which is nonimmunogenic on its own (hapten) to a larger immunogenic carrier molecule also achieves the same result. The most common routes of immunization are subcutaneous, intramuscular, intradermal, intraperitoneal and intravenous. Other routes of immunization include oral ingestion of antigen, antigen inhalation, topical application to the skin and the direct injection into an organ such

as the spleen. The dose of the antigen to be administered can profoundly influence the outcome of the procedure. Thus either very low or high doses of antigen may induce tolerance rather than the successful production of an antiserum. One should also bear in mind that with multiple injections, trace contaminants within an antigenic preparation may eventually elicit responses which will be detected in later bleeds collected from the animal and may result in an antiserum with multiple specificities. The degree of specificity of an antiserum depends largely on the degree of purity of the antigen used. The decision about antigen purity is often based on the intended use of the antiserum. If a highly specific antiserum that will only recognize the appropriate antigen is needed, then before commencing immunization the antigen must be purified to homogeneity.

Choice of species

Antisera can be raised in a wide variety of vertebrate animals: mice, rats, guinea pigs, hamsters, rabbits, chickens, sheep, pigs, goats, donkeys and horses. The choice of animal for immunization tends to be determined by how much serum is needed, how much antigen is available and the extent of foreignness of the antigen to the immunizing animal. Sheep, goats, pigs, donkeys and horses yield larger quantities of antiserum but are expensive to maintain and are generally used only for the production of commercially available antisera. Rabbits are most commonly used in the laboratory setting when individual investigators need to generate larger volumes of a particular antiserum. Exsanguination is the recommended method for collection of large amounts of antiserum from an animal to be sacrificed but this should only be performed by individuals well versed in the correct technique and as approved by institutional and national guidelines. The production of limited quantities of antisera in the mouse can be overcome by the production of ascites fluid where high antibody titers, equivalent to those achieved in serum, can be obtained. When only tiny amounts of antigen are available, the use of mice is also a clear advantage. A further advantage is that most investigators use inbred mouse strains and the genetics of the immune response for most of the strains have been well documented. If a weak response to an antigen is obtained in a particular mouse strain, changing the strain may help overcome the problem. If the amount of antigen is not limiting, several animals should be used as, even in inbred animal strains, a single antigen preparation will produce differing responses. The most important rule in the choice of animals is that immunization should be done in

animals that are furthest in evolutionary distance from the source of antigen.

Adjuvants

The judicious use of adjuvants (L. *adjuvare*, to help) allows for the generation of early, strong and sustained immune responses. In fact the use of an adjuvant can often determine the difference between success and failure. The adjuvants that are available are highly heterogeneous agents and exert their effects in diverse ways, such as causing depot formation at the site of injection (e.g. oil-based adjuvants), causing immunostimulation (e.g. lipopolysaccharide) and serving as delivery vehicles by facilitating the targeting of antigens (e.g. liposomes, biodegradable polymers). The most commonly used adjuvant is Freund's complete adjuvant, in which the immunogen is prepared as a water-in-oil emulsion. The main disadvantage of Freund's complete adjuvant is that it evokes aggressive granuloma formation in the animal and is thus completely unacceptable for use in human vaccine programs. A common alternative, and one licensed for human use, is alum. Here antigen is adsorbed on to an aluminum salt, aluminum hydroxide being most commonly used. Other adjuvants include Freund's incomplete adjuvant, N-acetylmuramyl-L-alanyl-D-isoglutamine (common name MDP) and its derivatives, lipid A, lipopolysaccharide, saponin, Quil A, ISCOMS, liposomes and micropheres made of biodegradable polymers. It should be stressed that the use of adjuvants is not only important for the humoral arm of the immune response (i.e. in generation of a superior antiserum) but also for activation of cellular immune responses. The single most important issue determining the acceptability of an adjuvant for human use is safety and the severity of side-effects, especially when implemented for routine childhood immunizations.

Uses of antisera

A final word about the use of antisera. They are used in medicine both for diagnostic purposes and for patient treatment, and in the laboratory they are used as analytical and preparatory tools. Thus the injection of antisera against toxins such as diphtheria and tetanus, against the venoms of snakes, and against rabies still remains a mainstay of treatment. Equally, the use of specific antiserum allows for the detection and quantitation of minute quantities of telltale antigens such as meningococcus in the cerebrospinal fluid or hormones and drug levels in urine or sera. Specific antisera are used for tissue typing and cells can be phenotyped using antisera raised against specific cell surface molecules. Antisera coupled to radionuclides are used in the detection and treatment of some tumors.

APOPTOSIS

Seamus J Martin, Molecular Cell Biology Laboratory, Maynooth College, Co Kildare, Ireland

In a multicellular organism cell death occurs in many contexts – during development, tissue homeostasis, terminal differentiation and disease. In most of these cases cells are eliminated due to the triggering of a process that results in the dismantling of the cell from within. This demolition process results in a very

distinctive and easily recognizable cellular phenotype that, in 1972, led John Kerr, Andrew Wyllie and Alister Currie to propose that this mode of cell death was different from that which occurred in response to severe cellular insults (necrosis), and for which they coined the term apoptosis. Apoptosis – a word

derived from the Greek where it is used to describe the process of leaves falling from trees or petals from flowers – perfectly encapsulates a process where cells quietly shrink and fall away from the tissues they were once an integral part of, with little damage to the main organism. Although the features of apoptosis were originally described in mammalian cells, the morphologic characteristics of dying cells are strikingly similar in birds, amphibians and insects. This suggests that at least some of the genes controlling this process have been well conserved through evolution, and indeed, evidence for this is now emerging.

Apoptosis can be triggered by diverse stimuli, both physiologic and pathologic, all of which seem to engage the same cellular machinery that is responsible for the destruction of the cell from within. Thus, although the proximal signaling events that can lead to apoptosis may vary from one stimulus to another, it is likely that different signals converge on a common set of effector molecules at some point. Recent developments in this field heavily implicate members of the interleukin 1 β (IL-1 β)-converting enzyme (ICE) family (caspases) as the end-stage effectors of apoptosis.

Apoptosis: form and function

Morphology

During apoptosis, a cell typically condenses its nucleus and cytoplasm, its DNA is degraded into many small (200 bp–250 kbp) pieces, marked blebbing of the plasma membrane occurs, and, in the final stages, the cell collapses into multiple intact fragments that are eaten by phagocytes *before* the cellular contents have had a chance to escape (Figure 1). Probably the most striking morphologic feature of apoptosis is the marked condensation and disintegration of the nucleus into numerous, intensely staining, spheres scattered throughout the cytoplasm

(A)

(B)

Figure 2 Morphological features of (A) a live versus (B) an apoptotic cell. Note particularly the disintegration of the nucleus into numerous discrete fragments.

(Figure 2). This contrasts starkly with the process of necrosis, where the nucleus typically swells to occupy most of the cytoplasm, and the chromatin decreases rather than increases in staining intensity. Plasma

Figure 1 Schematic representation of apoptosis.

membrane blebbing and disintegration of the cell into numerous apoptotic bodies are other highly characteristic features of apoptosis (Figure 3). The collapse of the cell into apoptotic bodies, that retain membrane integrity for several hours, likely facilitates phagocytosis and removal of the dying cell by surrounding phagocytes (Figure 1). In essence, apoptosis represents a clean and efficient way of removing unwanted or diseased cells while minimizing an inflammatory response.

Recognition and removal of apoptotic cells by phagocytes

Changes to the composition of the plasma membrane have long been suspected to mediate early recognition of apoptotic cells by phagocytes – thereby triggering their safe removal. In many ways this stage of apoptosis is the most critical, since the essential functional difference between an apoptotic and a necrotic cell is that the former is somehow recognized as being in the throes of death several hours before any cytoplasmic contents leak out. Necrotic cells, on the other hand, undergo early lysis, thereby

causing damage to surrounding cells and eliciting an inflammatory response. When apoptotic cells are formed in culture, where there are no phagocytic cells around to eat them, they eventually undergo secondary necrosis, which would probably be just as damaging as primary necrosis were it to occur *in vivo*. Thus, the membrane changes that signal to phagocytes that a cell is undergoing apoptosis are of paramount importance in this process.

Membrane changes that occur on apoptotic cells have proved elusive. To date it appears that there are two main alterations that occur on the surface of apoptotic cells that may be mutually exclusive in their usage. One mechanism used by apoptotic cells to signal their plight to surrounding cells is to export phosphatidylserine – a lipid normally confined to the inner plasma membrane leaflet on healthy cells – to the external surface of the plasma membrane. This appears to trigger phagocytosis of these cells, presumably by recognition of surface phosphatidylserine via a putative phosphatidylserine receptor on the macrophage. The other mechanism that has been comparatively well characterized involves the appearance of, an as yet unidentified, thrombospondin-binding ligand on the surface of the apoptotic cell. This ligand is bound by thrombospondin-bearing macrophages (thrombospondin being bound to the macrophage via a vitronectin receptor-CD36 interaction) and facilitates uptake of the apoptotic cell by the latter. Interestingly, the CD36-associated mechanism also appears to operate in *Drosophila*, as recent studies have discovered a CD36-related molecule (Croquemort) involved in macrophage removal of apoptotic cells in this organism. Other apoptosis-associated membrane changes have also been described, such as alterations to the carbohydrate composition of the plasma membrane, but these changes remain poorly characterized.

Figure 3 Transmission electron micrographs of a healthy (top) versus an apoptotic (bottom) mouse hepatocyte. Apoptosis was induced by ligation of CD95 (Fas/APO-1) on these cells with cross-linking antibody. Note the dramatic collapse of the apoptotic cell into many discrete apoptotic bodies (arrows) and the marked condensation of the chromatin (arrowheads). N, indicates the position of the nucleus in the live cell. (Reproduced with permission from Ni *et al.* (1994) *Experimental Cell Research* 215: 332–337. Figure kindly provided by Professor Shigekazu Nagata.)

Towards a molecular mechanism

Due to the widespread importance of apoptosis in many biological processes there has been intense interest in understanding how this process works at a molecular level. By 1993, although much of the cell biology of apoptosis had been established and several key apoptosis regulatory molecules, such as Bcl-2 and p53, had been discovered, very little was known concerning the nature of the cell death machinery itself. In 1993 a major breakthrough occurred when it was reported that CED-3, one of the genes that was known to be required for all the developmental-related programmed cell deaths in the nematode worm *Caenorhabditis elegans*, was homologous to ICE (caspase-1). ICE is a cysteine protease that has

been implicated in the processing of IL-1 β to its mature form and is unusual as it was the first protease described that cleaves after aspartate (Asp) residues. Recent studies suggest that ICE itself probably does not play a pivotal role in apoptosis: rather several of its mammalian homologs (including CPP32 (caspase-3), Mch2 (caspase-6), Mch3 (caspase-7) and mch5 (FLICE/Caspase-8)) are involved in the cell death signal. These caspases, which cleave after Asp residues, appear to be constitutively expressed in most cells as inactive precursors that require proteolytic processing to achieve their active forms (Figure 4).

Evidence that proteases are central to apoptosis

The evidence that proteases may be key components of the cell death machinery is derived from several lines of investigation. Early indications that proteases may participate in apoptosis was suggested by observations that several proteins underwent proteolytic cleavage during this process. Additional evidence was provided by the discovery that certain broad-spectrum protease inhibitors could block or delay apoptosis. Strong support for a role for caspases in apoptosis has subsequently been provided by studies that have examined the effects on apoptosis of CrmA, a cowpox virus-derived serpin (serine protease inhibitor) that was known for its ability to act as a pseudosubstrate for, and thereby neutralize, ICE. Several groups have independently reported that CrmA potently blocks several forms of apoptosis, including that induced by ligation of the CD95 molecule (Fas/APO-1) as well as due to CTL attack. Another pseudosubstrate for caspases was recently discovered in the form of the baculovirus

p35 protein, which was already known for its ability to act as a potent repressor of apoptosis.

Many recent studies have also found that specific peptide inhibitors of caspases (YVAD, DEVD, DEAD, VAD) inhibit many forms of apoptosis. All of this evidence for protease involvement in apoptosis is supported by the ongoing discovery of new proteins that are cleaved during this process. Together these data heavily implicate proteases as central components of the cell death machinery and suggest that the caspases play a critical role in apoptosis (Figure 5).

How protease activation may lead to the apoptotic phenotype

So how do proteases produce the apoptotic phenotype in a cell? The short answer is that we do not know as yet. Some informed guesses can be made by looking at the nature of the substrates that are cleaved during apoptosis. To date, most of the substrates that have been documented to undergo proteolytic cleavage during apoptosis are localized in the nucleus. It is likely that many of these cleavage events are not contributory to the apoptotic phenotype but are merely bystander effects due to these proteins possessing the appropriate cleavage sites. This idea is strongly supported by the observation that enucleated cells can also undergo apoptosis. However, it is relatively easy to conceive how cleavage of some of these proteins may directly lead to changes in the cell that frequently occur during apoptosis. For example, cleavage of the nuclear lamins, proteins that are largely responsible for the maintenance of the integrity of the nuclear envelope, could be directly responsible for the collapse (condensation) of the nucleus that is seen during apoptosis. Proteolysis of fodrin, a cytoskeletal protein that plays a major role in the cortical cytoskeleton, could lead to the plasma membrane blebbing that is typical of apoptosis (Figure 3). Proteases could also serve to degrade an inhibitor of the endonuclease that cleaves DNA at internucleosomal sites during apoptosis. Indeed, a protease with nuclease-activating properties has been described. Further studies are required in order to fully investigate the impact of each of the cleavage events upon cell integrity and to elucidate how they impact upon the cell death process.

Figure 4 Caspase (ICE/CED-3) family proteases require proteolytic processing to achieve their mature forms. Most caspases are probably constitutively expressed as inactive precursor proteins that require further proteolytic processing at Asp residues in order to achieve their active heterodimer forms (that may further associate to form dimers of heterodimers). Maturation of some caspases is seen during the early stages of apoptosis (CPP32 and Mch3, for example).

Apoptosis in immunity

In the immune system, apoptosis is used as a means to dispose of unwanted cells time and again. In many cases the CD95 molecule (Fas/APO-1), a member of the TNF/NGF receptor family, is used to transduce the death signal. Some of the situations where

Figure 5 Molecular events in apoptosis. Members of the caspase (ICE/CED-3) protease family are depicted as being at a point just below the convergence point for diverse proapoptotic stimuli. Activation of ICE/CED-3 family proteases may lead directly to the apoptotic phenotype through cleavage of specific substrates, although this is speculative. From current evidence, some apoptosis-repressor proteins (Bcl-2) appear to act upstream of the point of activation of at least some of the members of the ICE/CED-3 family, while others (CrmA, p35) act directly as inhibitors of these proteases.

apoptosis plays a key role in immunity are described below.

Thymic selection

It has been estimated that approximately 95–98% of thymocytes that enter the thymus are eliminated

there. Thymocytes die at several stages of the maturation process; either because they fail to rearrange their TCR genes successfully, because they exhibit strong reactivity with self (negative selection), or because they fail to recognize self-MHC at all (death by neglect). Studies in the late 1980s and the early 1990s established that thymocytes die in all of these cases due to the induction of apoptosis in these cells. Most of the cell deaths that occur in the thymus do so in the cortex and at the corticomedullary boundary at the double-positive stage ($CD4^+CD8^+$) of thymocyte development. Upon entry into the medulla, single-positive thymocytes ($CD4^+CD8^-$ or $CD4^-CD8^+$) become much more resistant to the induction of apoptosis. The precise nature of the signal that provokes death of cortical thymocytes has not been established. The possible involvement of CD95–CD95 ligand interactions is ruled out due to the fact that thymocyte maturation is largely unaffected in mice that carry loss-of-function mutations in CD95 (*lpr/lpr*) or the CD95 ligand (*gld/gld*). The thymocyte death signal is similarly unaffected by overexpression of Bcl-2, a 26 kDa protein that blocks many other forms of cell death.

Despite the enormous amount of cell death that goes on in the thymus, it is remarkable how few apoptotic cells are actually detectable in tissue sections of this organ. This puzzle can be explained if it is recalled that apoptotic cells are readily recognized by cells with phagocytic capability – by virtue of the membrane changes on these cells – and are eaten before they exhibit the morphologic features of apoptosis. Recent studies have implicated resident $F4/80^-$ macrophages as the effectors of this efficient clearance process for thymocytes undergoing negative selection, whereas $F4/80^+$ macrophages appear to remove thymocytes that have died by neglect.

Peripheral deletion

The small minority of thymocytes that are positively selected exit the thymus and migrate to the peripheral lymphoid organs. Here they are faced with the possibility of reacting with previously unencountered self-antigens. Should this happen, the autoreactive mature T cell, all going to plan, should then undergo apoptosis, probably as a result of receiving an inappropriate activation signal (such as TCR engagement in the absence of CD28 costimulation). Should this peripheral deletion process fail for any reason, then autoimmunity can result. Unlike in the thymus, CD95–CD95L interactions do appear to be important for peripheral deletion, as both *lpr* and *gld* mice are impaired in peripheral deletion and develop a systemic lupus erythematosus (SLE)-like autoimmune disease as a result.

Peripheral T and B lymphocytes are also eliminated after an immune response, otherwise the numbers of these cells would steadily increase after each successive encounter with antigen. While such an increase does happen to some extent (i.e. precursor frequencies to recall antigens are higher than to previously unencountered antigens), clearly the majority of clonally expanded lymphocytes do not survive long after an immune response has ended. Studies in recent years have established that these excess lymphocytes die by apoptosis. Once again, CD95–CD95L interactions have been implicated in this process. While mature peripheral T cells constitutively express CD95 on their surface, they are largely resistant to CD95L-mediated killing until they are activated, whereupon they now acquire sensitivity to CD95 ligation. Thus, activated T cells die upon encounter with CD95L-bearing cells. Since the expression of CD95L is strictly restricted to certain tissues, it is not clear what cells do the actual killing. It may be the activated T cells themselves, since CD95L is upregulated on lymphocytes upon activation, or a subset of dendritic cells or other antigen-presenting cells.

CTL and NK killing

Cytotoxic lymphocytes (CTLs and natural killer (NK) cells) are capable of killing target cells via two distinct pathways: by delivering cytotoxic granules on to the plasma membrane of the target cell, or by cross-linking the CD95 molecule on the target cell surface via CD95 ligand. In both cases, the end-result is the activation of the endogenous death machinery in the target cell, resulting in death from within – a kind of assisted suicide.

Granule-dependent killing is thought to be the major mechanism of cytotoxic lymphocyte killing. Cytotoxic cell granules contain perforin, a pore-forming protein similar to the C9 component of complement, as well as a series of enzymes – several of which are serine proteases – called granzymes. Perforin is thought to act as a conduit or channel to allow the entry of granzymes into the target cell cytoplasm. Of the seven or so granzymes that have been characterized to date, only one of these, granzyme B, has been shown to be both necessary and sufficient, in combination with perforin, to induce apoptosis of target cells. Granzyme B is an unusual protease in that it cleaves after Asp residues, a property that it shares with the caspase family of cysteine proteases discussed earlier. Recent studies have shed light on the mechanism whereby granzyme B activates the endogenous death machinery in the target cell. A number of groups have found that granzyme B is capable of directly cleaving and activating several

members of the caspase family, but not ICE itself. Thus, granule-dependent killing operates by directly activating the endogenous cell death machinery in the target cell by processing members of the caspase family to their active forms.

The other mechanism of cytotoxic lymphocyte killing involves a CD95 ligand-bearing cell interacting with, thereby cross-linking, CD95 on the target cell surface. As mentioned above, CD95 is a member of the TNF/NGF receptor family that transduces, upon trimerization, a death signal into cells bearing this receptor. CD95 was originally identified in 1989 by two separate groups and is commonly called two different names as a result: Fas or APO-1. The molecular mediators of the CD95-associated death signal have recently begun to emerge. Briefly, the cytoplasmic tail of CD95 contains a stretch of amino acids that are critical for the CD95-mediated death signal (the death domain), but this region does not have any obvious signaling function (such as kinase or phosphatase activity). Other death domain-containing proteins have since been discovered, such as FADD (Fas-associated death domain), that can associate with the CD95 death domain, thereby propagating the apoptotic signal. Thus, the death domain appears to be a protein–protein interaction domain. FADD then recruits caspase-8 (MACH-1/FLICE) which becomes processed to its active form, thus propagating the death signal.

Maintenance of immune privilege

It has been known for over a hundred years that certain sites in the body enjoy immune privilege. That is to say, immune responses do not generally occur at these sites. Classically, an immune-privileged site is defined as an area where introduction of allogeneic or xenogeneic cells does not result in immediate rejection as it would in other areas of the body. This definition has subsequently been broadened to include infectious organisms and tumors. Examples of immune-privileged sites include the eye, the testis and the central nervous system – all of which are tissues where the benefits of an immune response are outweighed by the dangerous consequences of a vigorous immune reaction in such delicate and vital tissues. While it was initially thought that immune privilege was maintained by physical barriers that contained antigen and prevented infiltration of the site by myeloid cells and lymphocytes, this is now known to be untrue because these cells do enter privileged sites but are somehow inactivated. Recent studies on the eye and the testes appear to have solved this puzzle. In these organs, it transpires that CD95 ligand is abundantly expressed such that infiltrating lymphocytes and neutrophils – both of which

express surface CD95 – are induced to undergo apoptosis upon entry into these sites. As elegant proof of this, mice carrying a non-functional CD95-ligand (gld) do not enjoy immune privilege and, in the case of the eye, display marked infiltration upon introduction of a virus (herpes simplex virus type 1, HSV-1) into the anterior chamber of this organ – resulting in keratitis. In stark contrast, introduction of HSV-1 into the eye of wild-type mice results in death of infiltrating lymphocytes and neutrophils and containment of the infiltrating cells to the anterior chamber. Similarly elegant transplantation experiments of testes from *lpr* and *gld* mice yielded a similar conclusion that CD95 ligand was responsible for maintaining immune privilege in this organ also. Other studies have demonstrated that CD95L is also abundantly expressed in other immune-privileged sites such as the brain, ovary, uterus, adrenal gland and prostate, suggesting that a similar protective mechanism from immune responses operates in these tissues also.

B cell development and affinity maturation

Like T lymphocytes, the majority of newly formed B lymphocytes fail to migrate to the peripheral lymphoid organs due to the induction of apoptosis in these cells. B cells are produced throughout life in the bone marrow but only a small minority of these cells, as is the case with thymocytes, will be allowed to enter the peripheral blood. Most developing B-lineage cells die by apoptosis, either because of aberrant immunoglobulin (Ig) gene rearrangements or due to encounter with high concentrations of high-affinity antigens (akin to negative selection). It has been estimated that approximately 75% of developing B cells die in the bone marrow at the transition between large pro-B to small pre-B cell stage. The small fraction of virgin B cells that exit the bone marrow travel to the spleen and then on to the lymph nodes. In the peripheral lymphoid tissues B cells fall into two compartments, short-lived (2–3 days) and long-lived (several weeks). Short-lived B cells probably die (by apoptosis) through failure to encounter antigen and are rapidly replaced by newly formed B cells from the bone marrow. B cells that receive a survival signal (antigenic stimulation) likely switch to the long-lived state, although there has been some debate concerning whether short-lived and long-lived B cells are derived from separate bone marrow precursors or a common progenitor. In either case, long-term survival of B cells appears to require repeated re-stimulation with antigen. Long-term B cell survival appears to be regulated, at least in part, by expression of the Bcl-2 protein. Bcl-2 transgenic mice

display elevated peripheral B cell numbers and extended B cell memory.

B cells that manage to persist also run the gauntlet of apoptosis during affinity maturation in the germinal centers. During the germinal center reaction, activated B cells acquire point mutations in the V regions of their immunoglobulin genes that may or may not increase their affinity for antigen and can even result in autoreactivity. The majority of B cells that undergo this hypermutation process are eliminated via apoptosis, with mutants that have a high affinity for antigen being rescued from a similar fate due to encounter with their specific antigen in the context of CD40 ligand (gp39) costimulation. CD95 also appears to play a role in this elimination process because activated B cells acquire sensitivity to CD95 unless they receive concurrent engagement of the CD40 molecule. This may also explain why *lpr* mice (that are defective in CD95) also display a B cell defect and develop an SLE-like autoimmune disease.

Resolution of inflammation

One of the earliest events in an immune response involves the dramatic accumulation of infiltrating neutrophils and other cells of the myeloid lineage at the site of infection. Neutrophils form a very important first line of defense and these cells appear to be well equipped for this task, with a barrage of toxic enzymes and reactive oxygen intermediates within their secondary granules. But what happens to all of these cells when they have completed their task and are no longer required? It is well known that neutrophils have a very short half-life of approximately 12–18 hours. But where do they die and how are they disposed of? By now it will come as no surprise to learn that old unwanted neutrophils die by apoptosis and that damage to cells in the vicinity of dying neutrophils is minimized as they are programmed to die around the time that the wave of macrophage infiltration reaches its peak. Thus, inflammatory macrophages are charged with the task of removing the dying neutrophils and of safely disposing of their potentially destructive contents. The trigger for macrophage recognition of senescent neutrophils, as discussed earlier, appears to be either phosphatidylserine externalization at the surface of the plasma membrane or the appearance of a thrombospondin-binding moiety on the surface of these cells – depending on whether the phagocytic cells are inflammatory or resting macrophages, respectively. Interestingly, macrophages respond very differently when they phagocytose apoptotic cells, as opposed to yeast particles, for example, as the former do not elicit the release of inflammatory mediators by the

macrophage. Whether a distinct phagolysosomal compartment is used for digestion of apoptotic cells has not been explored as yet.

Apoptosis in disease

We now know that proper control of cell death is just as important for the maintenance of dividing cell populations at equilibrium as control of cell division is. Therefore, just as loss of normal controls on cell division can result in disease, so can defects in the regulation of cell death. Obviously, cell death defects can take two forms – too much or too little. Situations where excessive or inappropriate apoptosis may contribute to disease include neurodegenerative diseases such as Alzheimer disease, Parkinson disease and spinal muscular atrophy. In the latter case, this appears to be due to loss-of-function mutations in an endogenous inhibitor of apoptosis (neuronal apoptosis inhibitory protein). It has also been proposed that the loss of CD4⁺ T cells that is observed during human immunodeficiency virus (HIV)-1 infection is due to excessive apoptosis (although this is a debatable point). The development of some forms of autoimmunity may either be the result of a block in apoptosis – that allows autoreactive lymphocytes to survive – or defective apoptosis – that allows the release of proteins that could potentially break self-tolerance. On the other side of the coin, over-expression or dysregulation of genes that can block apoptosis (such as bcl-2 or bcr-abl) or mutations in genes that can facilitate apoptosis (p53) may also contribute to the development of malignancy by synergizing with proliferation-associated oncogenes (such as c-myc). Thus, intensive investigation is currently underway to understand how apoptosis works at a molecular level and to explore how this process can be modulated in situations where this may be desirable.

ARACHIDONIC ACID AND THE LEUKOTRIENES

Marek Rola-Pleszczynski, Faculty of Medicine, Université de Sherbrooke, Sherbrooke, Quebec, Canada

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Arachidonic acid (AA) is an important constituent of mammalian cell membranes. Following membrane perturbations or receptor-mediated signaling which leads to activation of phospholipase A₂ (PLA₂), AA is released from membrane phospholipids. It may undergo oxidative metabolism through cyclo-oxygenase, which results in the formation of the various prostaglandins, through the cytochrome P450 system, or through one of several lipoxygenases. Borgeat and Samuelsson first identified a novel class of molecules derived from this latter metabolic pathway of AA, which they named leukotrienes, because of their leukocytic origin and their characteristic triene structure. Leukotrienes (LTs) are derived from the combined actions of 5-lipoxygenase (5-LOX) and 5-LOX-activating protein (FLAP), with initial formation of 5-hydroperoxyeicosatetraenoic (5-HPETE) acid, followed by LTA₄. LTB₄, which is an enzymatic, hydrolytic product of LTA₄, differs from the other leukotrienes, LTC₄, LTD₄ and LTE₄, in that it has no peptidic component. It is a more stable molecule than the peptidoleukotrienes, but can be rapidly degraded through ω -oxidation by polymorphonuclear leukocytes (PMNs) to the relatively inactive metabolites, 20-OH-LTB₄ and 20-COOH-LTB₄.

While sharing some of the myotropic properties of the other leukotrienes, LTB₄ has been found to exert very strong leukocytotropic activities. It is one of the most powerful chemokinetic and chemotactic agents and it can induce neutrophil aggregation, degranulation, hexose uptake and enhanced binding to endothelial cells. It can also induce cation fluxes, augment cytoplasmic calcium concentrations from intracellular pools and activate phosphatidylinositol hydrolysis. LTB₄ can also synergize with prostaglandins E₁, (PGE₁) and PGE₂ in causing macromolecule leakage in the skin, through increased vascular permeability, and, when injected into guinea pig skin, it induces leukocytoclastic vasculitis. Two sets of plasma membrane receptors for LTB₄ have been described on human PMNs. The high-affinity receptor set mediates aggregation, chemokinesis and increased adherence to surfaces, while the low-affinity receptor set mediates degranulation and increased oxidative metabolism. In contrast to human cells, rat leukocytes lack the lower affinity receptor set. Signal transduction via high-affinity receptors appears to involve

a guanine nucleotide regulatory protein. In contrast to PMNs, little is known at present about potential LTB₄ receptors on lymphocytes, although a fraction of CD4⁺ and CD8⁺ T cells bind LTB₄.

Cellular sources of LTB₄

LTB₄ is rapidly synthesized by phagocytic cells, principally PMNs and alveolar macrophages, upon challenge with a variety of stimuli such as microbial pathogens, toxins, aggregated immunoglobulin, tumor necrosis factor α (TNF α), particulate material or ionophores, especially when exogenous AA is available. Its synthesis can also be induced by platelet-derived 12-HPETE or platelet-activating factor (PAF). Induction by natural stimuli of LTB₄ production by PMNs *in vitro* is relatively modest, unless the cells are primed by granulocyte-macrophage colony-stimulating factor (GM-CSF), TNF α or bacterial lipopolysaccharide (LPS) (Table 1). Under these conditions, enhanced LTB₄ production appears to be the result of both an immediate activation of PLA₂, with subsequent generation of AA, and a later, transcriptional induction of 5-LOX and FLAP gene expression. In contrast, PMNs exposed to transforming growth factor β (TGF β) lose the capacity to produce LTB₄ through a selective downregulation of 5-LOX (but not FLAP) mRNA expression. Such an interaction between priming events and direct stimuli of LT generation may also be operative *in vivo* in the context of infection and inflammation.

LTB₄ is predominantly a product of cells of myeloid origin. PMNs are the main source of the mediator: when stimulated by LPS, PMNs can produce five times more LTB₄ than monocytes. In con-

Table 1 Production of LTB₄ by PMNs as a function of stimulus and priming

Stimulus	Priming	LTB ₄ production
Ca ²⁺ ionophore	–	++
PAF or fMLP	–	±
PAF or fMLP	GM-CSF, TNF α or LPS	++
PAF or fMLP	TGF β	–

fMLP, N-formylmethionine leucine phenylalanine.

trast, the latter produce a wider variety of AA metabolites, including the peptido-LT and prostanoids. B lymphocytes can also produce LTB₄ and 5-HETE. Unlike PMNs or monocytes, they require particular stimulation conditions, including an oxidative environment, in addition to a source of AA. T lymphocytes, on the other hand, do not produce LTs, as they lack 5-LOX. Similarly, endothelial cells and epithelial cells of different origins cannot directly synthesize LTB₄ from AA, because they lack both 5-LOX and FLAP (Table 2). They can and do, however, produce LTB₄ when supplied with LTA₄, through what is known as transcellular metabolism, since they have LTA₄ hydrolase. That the genes involved in LT synthesis can be derepressed is suggested, however, by the observed production of LTC₄ by a human hybridoma formed by fusing CD8⁺ T cells with CD4⁺ CEM-6 lymphoma cells.

LTB₄ has been detected in significant concentrations in inflammatory synovial exudates, psoriatic skin lesions, peritonitis and inflammatory bowel disease. In an animal model of colitis, local production of LTB₄ and LTC₄ correlates with inflammatory cell infiltrates. Globally, LTB₄ thus appears to be a potent proinflammatory agent. It may also affect many immunoregulatory functions via interactions with a variety of cell populations, as presented in the next sections.

Cellular actions of LTB₄

T lymphocytes

When LTB₄ is added to human peripheral blood mononuclear leukocyte cultures stimulated with mitogenic lectins, an inhibition of the proliferative response can be observed. Similar findings are also observed for LTD₄ and LTE₄, and for 15-HETE in mice. A significant suppressor cell activity can indeed be generated at picomolar concentrations of LTB₄.

Table 2 Expression of 5-LOX and FLAP in various cell populations

Cell population	FLAP	5-LOX
PMNs	+	+
Monocytes/macrophages	+	+
Myeloid cell lines		
THP-1	—	+
U937	+	—
HL-60 (differentiated)	+	+
B cells/B cell lines	+	+
T cells	±	—
T cell lines (Jurkat, MOLT)	+	—
Endothelial cells	—	—

LTD₄ induces no such suppressor cell activity. The magnitude of the suppressor cell activity generated by LTB₄ is comparable to that seen with histamine, but the concentrations at which it occurs are orders of magnitude lower than those needed with the latter. LTB₄-induced suppressor T cells can also inhibit immunoglobulin production by B cells and leukocyte migration inhibitory factor production by T cells.

When LTB₄ induces the appearance of suppressor cells, the effective suppressor cells bear finally the CD8⁺ phenotype. Proliferation of CD4⁺ cells is inhibited by LTB₄, whereas the proliferation of CD8⁺ cells is enhanced. Further analysis of the cellular requirements for LTB₄-induced suppressor cell activity reveals that, whereas only T cells need to interact with LTB₄, the expression of their suppressor activity requires the presence of monocytes in the responding cell population. Only purified CD8⁺ T cells can bypass this requirement. For preincubated CD4⁺ T cells or unfractionated T cells, little suppression is seen in the absence of monocytes, whereas a helper effect is evident in the presence of monocytes plus the cyclo-oxygenase inhibitor indomethacin. This phenomenon could be explained by a dual stimulation of monocytes to produce both PGs and interleukin-1 (IL-1) by LTB₄-preincubated T cells. Indeed, LTB₄-pulsed T cells release a soluble factor which stimulates monocytes to produce PGE₂ and/or IL-1, and most of the activity of such T cell supernatants is attributable to interferon γ (IFN γ). LTB₄ can indeed enhance, at nanomolar concentrations, IFN γ production by CD4⁺ T cells and inhibit IFN γ production by CD8⁺ T cells. In the mouse, LTB₄ (as well as other leukotrienes and AA itself) can replace a requirement for helper cells or IL-2 in IFN γ production. LTB₄ can also induce proliferation of IL-2-dependent T cells in the presence of suboptimal IL-2 and restore such proliferation after inhibition with lipoxygenase inhibitors or hydrocortisone. LTB₄ can also induce T cells to produce IL-2 and IL-5 (Figure 1).

B lymphocytes

Purified human B cells show amplified proliferative responses to IL-2, IL-4 and B cell stimulatory factor, when exposed to picomolar concentrations of LTB₄. Immunoglobulin G (IgG) production is also enhanced by LTB₄, but not by LTC₄. Moreover, in the presence of IL-4, LTB₄ stimulates IgE production, suggesting a central role for this mediator in allergy. In contrast, LTC₄ can affect B cells directly and suppress Ig production. LTB₄ also induces enhanced CD23 and major histocompatibility complex (MHC) class II antigen expression on B cells (Figure 1).

Figure 1 Stimulatory proteins of LTB_4 on cells of the immune system.

NK cells

LTB_4 can modulate the activity of natural killer (NK) and natural cytotoxic (NC) lymphocytes. At picomolar concentrations, LTB_4 and, to a lesser extent, LTA_4 , markedly augment NK and NC activities. Lipoxygenase inhibitors can reversibly block NK and NC activity, and this inhibition can be effectively reversed by LTB_4 , indicating that exogenous lipoxygenase products can compensate for endogenous lipoxygenase inhibition. However, whereas human NK cells pretreated with interferons or poly I:C are partially resistant to suppression by lipoxygenase inhibitors, lymphokine (IL-2)-activated killer (LAK) cells can be reversibly inhibited by these drugs. LTB_4 acts on effector NK or NC lymphocytes rather than on their target cells, increasing both the binding of effector lymphocytes to their target cells and the rate of target cell killing. No IL-2 or IFN γ is detectable in these cultures.

LTB_4 can also enhance IL-2-induced cytolytic activity on both NK (CD56 $^+$) cells and cytotoxic T

(CD8 $^+$) cells. Twenty-four hours after exposure to 10^{-10} M LTB_4 , the cells respond to 100-fold lower concentrations of IL-2 with enhanced cytotoxicity. This is accompanied by an LTB_4 -dependent increase in expression of IL-2R β on CD56 $^+$ and CD8 $^+$ cells, suggesting a receptor-mediated sensitization of NK and cytotoxic T cells (Figure 1).

Monocytes/macrophages

Cytotoxicity The potential regulatory role of endogenous and exogenous LTs on functions of monocytes/macrophages has also come under study, in view of the findings that LTs are synthesized and released by these cells after receiving immunological and nonimmunological stimuli. For instance, as assessed by use of lipoxygenase inhibitors, activation of macrophage phagocytic capacity by endotoxins appears to be dependent on lipoxygenase metabolites of AA. LTs can also induce the release of PGs and lysosomal enzymes by macrophages. When appropriately stimulated, monocytes/macrophages can pro-

duce a variety of cytokines, as well as inhibit tumor cell growth or destroy susceptible target cells by a number of different mechanisms. For instance, when mouse-resident peritoneal macrophages are cocultured with MOPC-315 myeloma cells, the cytostatic activity of the former is enhanced by either LTD₄ or indomethacin, whereas both LTD₄ and indomethacin together are additive in causing a more than 80% inhibition of tumor cell proliferation.

Human peripheral blood monocytes can also lyse several types of tumor target cells. When they are incubated with LTB₄, a very significant augmentation of cytotoxicity is observed. This is associated with enhanced binding of monocytes to target cells and augmentation in the rate of killing of target cells by the culture supernatants. Inhibitors of lipoxygenase cause a marked inhibition of monocyte-mediated cytotoxicity. Exogenous LTB₄ can restore the activity, suggesting that both endogenous and exogenous LTs have a positive effect on cytotoxic functions of mononuclear phagocytes.

Cytokine production LTB₄ is a powerful stimulator of IL-6 production by monocytes. At nanomolar concentrations, LTB₄ induces a fivefold increase in IL-6 gene transcription and a threefold extension of IL-6 mRNA half-life. This effect is dependent on activation of a tyrosine kinase and involves induction of the transcription factors NF- κ B and NF-IL6. Although LTB₄ also stimulates the accumulation of IL-1 β mRNA, it preferentially augments IL-6 production as compared to IL-1. LTB₄ can also affect cytokine production indirectly, via T lymphocyte activation: human T cells pulsed with LTB₄ modulate IL-1 production by human monocytes by secreting IFN γ .

TNF α is a potent mediator of cytotoxic activity exerted by monocytes and macrophages, as well as NC lymphocytes. LTB₄ markedly enhances cytotoxicity mediated by NC cells and monocyte-mediated cytotoxicity is also augmented by LTB₄. Addition of LTB₄ to monocyte cultures enhances TNF α activity of their supernatants. Addition of indomethacin to the cultures augments TNF α production, whereas lipoxygenase inhibitors diminish TNF α production. LTB₄ may thus affect cytotoxic activity of human monocytes by augmenting their production of the cytolytic cytokine TNF α .

Alveolar macrophages can play a crucial role in the pathogenesis of pulmonary disease via their ability to produce potent inflammatory and fibrogenic mediators. When alveolar macrophages are cultured with silica particles or asbestos fibers they produce TNF α and LTB₄ in a concentration-dependent fashion. Increased amounts of LTB₄ precede the

rise in TNF α activity. The lipoxygenase inhibitors NDGA and AA861 reduce in a concentration-dependent fashion asbestos- or silica-stimulated TNF α release. On the other hand 'reconstitutive' experiments in which exogenous LTB₄ is added to alveolar macrophages treated with lipoxygenase inhibitors show partial restoration of TNF α production induced by chrysotile or silica. Alveolar macrophages are also stimulated by PAF to produce IL-1 β , TNF α and IL-6. Lipoxygenase inhibitors, including the FLAP antagonist MK-886, prevent this effect of PAF, whereas exogenous LTB₄ partially reconstitutes the responses.

LTB₄ can induce the expression of IL-2R α in human monocytes by activating IL-2R α gene transcription. It can also stimulate the expression of IL-2R β through post-transcriptional regulation. This augmented expression of both α and β chains of IL-2R is associated with enhanced sensitivity of monocytes to IL-2 in terms of TNF α production, and may be relevant to some of the proinflammatory actions of LTB₄.

In addition to modulating cytokine production and cytokine receptor expression, LTB₄, as well as LTC₄ and LTD₄, can stimulate human myelopoiesis and play a role as essential intermediates in GM-CSF-stimulated myeloid colony formation.

Polymorphonuclear leukocytes

AA induces PMNs to aggregate, generate superoxide anion and release the contents of lysosomes, by mechanisms which do not appear to involve any of its metabolites. LTB₄ also activates PMNs in a number of ways: it induces chemotaxis, aggregation, degranulation, cation fluxes and superoxide anion production. LTB₄ induces migration and adhesion of PMNs to endothelium, secondary to expression of CD11/CD18 adhesion molecules. Moreover, LTB₄ constitutes a powerful stimulus for its own production, as well as for the production of PMNs of certain cytokines, in particular IL-8.

AA and LTs as second messengers

AA can exert a variety of direct effects on leukocytes that do not depend on the metabolism via cyclooxygenase or lipoxygenase pathways. AA can directly activate protein kinase C, an effect it shares with diacylglycerol. AA can also directly activate a pertussis toxin-sensitive GTP-binding protein in the PMN plasma membrane and may thereby act as a second messenger in signal transduction.

LTB₄ and possibly other 5-LOX metabolites may also play central roles as internal 'second messengers'. LTB₄ can induce *c-fos* and *c-jun* proto-

oncogene expression in monocytes and PMNs. This is accompanied by enhanced binding of LTB₄-induced nuclear proteins to the AP-1 consensus site, suggesting that LTB₄ may play a role in the transactivation of genes containing the AP-1 binding site in their promoter region. Through intracellular formation of H₂O₂, LTB₄ can also activate the transcription factors NF-κB and NF-IL6.

LTB₄ may also play a role as an endogenous Ca²⁺ ionophore, and the sensitivity to LT synthesis inhibition of a number of cellular responses to a variety of stimuli strongly suggests that LTs may act as second messengers for the regulation of certain immune functions, including cytokine production. The recent development of a 5-LOX knockout mouse model should prove particularly useful in defining the selective involvement of LTs in immune and inflammatory conditions.

Conclusion

An increasing body of evidence suggests that LTB₄ may be an important modulator of many immune cell functions, either as an internal messenger within

some cells, or as an external signal, linking inflammatory cells to lymphocytes. LTB₄ and, to some extent, other LTs, are known protagonists of numerous inflammatory processes. They can also mediate varied and powerful effects on many cells involved in immunological reactions.

ARENAVIRUS, INFECTION AND IMMUNITY

Maria S Salvato, Pathology Department, University of Wisconsin Medical School, Madison, Wisconsin, USA

Igor S Lukashevich, Belarussian Research Institute for Epidemiology and Microbiology, Minsk, Belarus

Discussions of cell-mediated immunity and immunopathogenesis frequently cite the prototype arenavirus, lymphocytic choriomeningitis virus (LCMV). The 1996 Nobel Prize in Physiology or Medicine went to Peter Doherty and Rolf Zinkernagel who used LCMV-infected mice to show that cytotoxic T lymphocytes (CTLs) only kill cells that are syngeneic at the major histocompatibility complex (MHC) (murine H2) locus. Two properties of LCMV facilitated this landmark finding: first, LCMV is non-cytopathic in cell culture, enabling 15 h chromium-release assays in which cell lysis is entirely due to CTLs, and second, LCMV elicits a vigorous CTL response, peaking 7 days after infection and causing very high specific lysis in chromium-release assays. Several other viruses elicit cell-mediated immunity, but usually their virus-specific CTL activity cannot be detected without secondary stimulation. This entry summarizes research primarily on the less viru-

lent arenaviruses – LCMV, Pichinde and Tacaribe – and, to a lesser extent, on the virulent ‘emerging viruses’ such as Lassa, Machupo, and Junin.

Characteristics of the arenaviruses and their antigens

The arenaviruses are enveloped viruses with two single-stranded RNA genomic segments. They are classified as ‘negative-strand viruses’ because their genomic RNA cannot function as a messenger RNA, i.e. transcription by the viral RNA-dependent RNA polymerase (RdRp) must precede translation. The arenaviruses encode four gene products; a nucleocapsid protein (NP) that encapsidates the genomic RNA, an envelope glycoprotein (GP) that undergoes a maturation cleavage to become GP1 and GP2, a small zinc-binding protein (Z) and a large RdRp (L). The small (S) RNA segment is 3.4 kb and encodes

Figure 1 The arenaviruses are noncytopathic and bud from the host cell. They have a granular appearance from which the name (*L. arena*, sandy) is derived. (Reproduced by permission from M Buchmeier, La Jolla, CA.)

GP and NP in an ambisense arrangement (using sense and antisense (complementary) mRNAs). The large (L) RNA segment is 7.2 kb and encodes the Z and L proteins, also in an ambisense arrangement. The morphological characteristics of arenaviruses are depicted in Figure 1.

Immune responses of the host

Arenaviruses are generally carried by rodents with little ill-effect to the carrier; however, transmission from rodents to primates can cause severe encephalitis, hepatitis or hemorrhagic syndrome. Thus, rodent and humans can have drastically different immunologic and pathologic responses to infection. We will describe the classical studies of cell-mediated immunopathology in the LCMV/murine model with the caveat that it does not apply to arenavirus disease in primates.

LCMV was first isolated in the early 1930s from a man who died of encephalitis in St Louis, Missouri. It was never entirely clear whether the virus came from the deceased person or from the laboratory mice used for passage, because similar stocks of LCMV were isolated from mice in other laboratories around the same time. Electron microscopy and serological studies confirmed the familial relatedness of the various laboratory isolates and some new viruses from outbreaks in Africa (Lassa virus) and South America (Machupo and Junin).

Ever since the 1960s, LCMV was used to study virus-induced cell-mediated immunity. There are two types of murine infection: an acute infection that correlates with vigorous cell-mediated immunity (as measured by CTL assay) or a persistent infection that correlates with little cell-mediated immunity (Figure 2). The immune response to the acute infection either kills the mouse by engendering meningitis, or subsides and leaves the mouse LCMV-immune. Adoptive transfer of splenocytes from an LCMV-immune mouse can clear infection in a persistently infected mouse. Clearance is mediated by CD8⁺ and not

CD4⁺ splenocytes, as shown by antibody depletion of lymphocyte subsets. In contrast to their beneficial effects in clearing virus infection, the CD8⁺ cells mediate pathology (choriomeningitis) when injected intracerebrally. Thus the LCMV/murine model offered a paradigm for the positive and negative effects of CTL-mediated immunity. Even though LCMV has an acid-sensitive envelope, it has recently been shown to infect the gastric mucosa at very low doses; thus expanding its usefulness to studies of mucosal immunity.

LCMV-specific cell-mediated immunity was defined by studies with transgenic mice, synthetic peptides, and recombinant vaccinia expression vectors. BALB/c (H-2^d) mice make a CTL response primarily to epitopes on the viral envelope, GP, whereas C3H (H-2^b) mice respond primarily to epitopes on the NP. Synthetic peptides were used to define the most important residues for these CTL epitopes. Transgenic mice lacking CD8⁺ expression (either by CD8 gene knockout or by knockout of β_2 -microglobulin) have greatly reduced CTL responses, resulting in virus persistence. Intracerebrally infected mice lacking CD8⁺ lymphocytes die later than normal mice, thus the CD8-mediated immunopathology is reduced but not entirely eliminated. Knockout mice lacking perforin are also unable to clear infections, indicating that virus clearance is dependent on the perforin-mediated destruction of virus-infected cells. Mice lacking CD4⁺ cells or B cells are able to clear virus-infected cells initially, but virus reappears and the mice then succumb to acute infection.

LCMV infection induces inflammatory intermediates such as interferon γ (IFN γ) and tumor necrosis factor α (TNF α), both of which influence the host's immune response to other pathogens. IFN γ stimulates the proliferation of natural killer (NK) cells that serve to eliminate certain pathogen-infected cells and some tumors. TNF α produced in the liver as a result of LCMV infection can clear hepatitis B virus infection, even in perforin-negative mice, probably by

Figure 2 In the murine/LCMV model, acute and persistent infections are correlated with vigorous and poor virus-specific CTL responses, respectively. Acute infection generally requires an adult immunocompetent mouse, whereas persistent infection generally occurs in a neonatal or immunosuppressed mouse, or in an adult mouse given an immunosuppressive variant of LCMV. Vigorous CTL response can mediate lethal immunopathology, but adoptive transfer of CTL can also mediate virus clearance.

inducing an RNase that destroys the hepatitis viral nucleic acid.

Junin, Machupo and Lassa viruses can cause hemorrhagic fever in primates, the severity of which is directly proportional to virus titer. Arenavirus disease in primates is not alleviated by immunosuppressive cyclophosphamide. The Junin and Machupo diseases are primarily treated with convalescent serum, whereas Lassa disease is primarily treated with ribavirin, since antisera are only effective early in the disease.

Virus evasion of host immune responses

The ability of arenaviruses to persist in their long-term carriers is facilitated by antigenic variation that allows evasion of host immune responses. Neutralization-resistant variants of Junin and Tacaribe viruses escape the humoral immune response, and certain

epitope variants of LCMV escape the CTL response. In addition to viral variants that can escape host immune surveillance, variants have been described that suppress the immune response and thereby persist. Docile is a variant of the Aggressive isolate of LCMV (UBC), and Clone 13 is a variant of the LCMV (Armstrong strain). Both Docile and Clone 13 replicate very well in the spleen and poorly in the brain in contrast to their parental viruses. Both Docile and Clone 13 elicit poor CTL responses when tested 7 days after infection, and consequently, both persist in the mouse longer than their parental viruses. Docile and Clone 13 isolates actually do elicit CTL by day 3 after infection, but these viruses replicate so vigorously in the spleen that they cause high-dose immune suppression, i.e. high immune stimulation leading to massive apoptosis of immunocytes, leading to little CTL response by day 7. Thus, virus isolates that were thought to be immunosup-

pressive are in fact evading host immune responses by overstimulating and destroying the immune response.

Vaccines

Mice can be protected from lethal LCMV challenge either by peptide vaccination or by vaccinia vectors that express viral epitopes. Guinea pigs can be protected from lethal Lassa virus challenge by inoculation with vaccinia vectors that express either Lassa glycoprotein or Lassa nucleoprotein; however primates are only protected by the vector expressing glycoprotein. Primates are protected from the Junin virus disease, Argentine hemorrhagic fever, by injection with attenuated strains of Junin or with the related strain Tacaribe. Tacaribe or its subunits would make an excellent vaccine for Argentine hemorrhagic fever because it is unlikely to revert to pathogenicity, and causes a brief infection.

Vaccine research using arenaviruses established important negative as well as positive results. Vaccination of guinea pigs with both the Lassa NP and GP-expressing vector does not give double protection against virus challenge, but instead gives less protection than a single vaccination. Vaccination of mice with a GP-expressing vector can sometimes exacerbate virus-mediated pathogenesis. Despite the setbacks, there is considerable optimism that effective subunit vaccines may eliminate some problems that arise when attenuated viral strains are used for vaccination.

ARGININE AND IMMUNITY

Stephen J Kirk and Adrian Barbul, Department of Surgery, Sinai Hospital and The Johns Hopkins Medical Institutions, Baltimore, Maryland, USA

Arginine, a dibasic nitrogen-rich amino acid, is classified as semidispendable. In health it is synthesized in adequate amounts for the maintenance of nitrogen balance. Dietary requirement is essential only for the optimal growth of the young of some species. In certain circumstances, such as immaturity and severe stress (sepsis, trauma, nitrogen overload), arginine becomes indispensable, being required for maintenance of nitrogen balance and physiologic functions in humans. More importantly, arginine has

several unique and remarkable pharmacologic properties, including a marked immunomodulatory function.

Immune function

Supplemental administration of arginine (approximately 500 mg kg⁻¹ per day) to rodents either enterally or parenterally enhances thymic size, lymphocyte count and lymphocyte mitogenesis in

response to mitogens and alloantigens. This is accompanied by enhanced interleukin 2 (IL-2) synthesis. Following injury, arginine reduces or abrogates post-traumatic thymic involution and the impairment of T lymphocyte function. Other immune effects of arginine include enhanced delayed-type hypersensitivity reactions, amplified *in vitro* and *in vivo* allogeneic responses and increased survival following lethal septic challenges, experimental burn injuries and trauma. Arginine also promotes host antitumor responses in a variety of tumor models (solid transplanted, chemical- or viral-induced) by decreasing the rate of tumor growth and metastatic spread, and by increasing the latency period to tumor appearance following induction. Survival is also increased. Similarly, in humans, supplemental arginine stimulates T lymphocyte mitogenesis, increases T helper to T suppressor cell ratio and improves wound healing.

Arginine is required *in vitro* for optimal lymphocyte mitogenic response, cytokine production, and for induction of cytotoxic T lymphocyte (CTL) and natural killer (NK) cell function. Maximum mitogenic stimulation and IL-2 production occur at an arginine concentration of 0.04 mM, further increases do not result in enhanced responses. Maximal NK and CTL generation and activation *in vitro* is observed at an arginine concentration between 0.4 and 0.9 mM. Plasma arginine concentrations in human adults range from 0.04 to 0.1 mM, suggesting that the effects observed with *in vivo* arginine supplementation are not related to elevation of plasma levels, since they are already optimal for lymphocyte function.

Within the rodent immune system macrophages, neutrophils and lymphocytes utilize the arginine-nitric oxide (NO) pathway. In macrophages this pathway is essential for the expression of cytotoxicity against tumor cells and pathogenic fungi. Inhibition of NO generation using a specific inhibitor (L-mono-N-methylarginine) results in abrogation of cytotoxic response. Cytotoxic macrophages generating NO destroy target cells by inhibiting aconitase activity (a citric acid cycle enzyme), DNA synthesis, and mitochondrial respiration. A similar pathway has been identified (*in vitro*) in cloned T cells. In these cells NO has an autocrine function in the regulation of cell mitogenesis. The role of the arginine-nitric oxide pathway in humans is less well defined.

The presence of arginine is essential for the function of a variety of immunoregulatory proteins such as thymosin, thymopentin and tuftsin. Production of activated C3a and C5a (both powerful vasoconstrictors and fundamental in the inflammatory process) occurs when the C3 and C5 α chains, respectively,

are split at the N-terminal end by convertase enzymes, thus exposing a C-terminal arginine molecule. Subsequent arginine removal by carboxypeptidase B inactivates C3a. Removal of the arginine from C5a produces C5a-desarginine, which maintains (at a much reduced level) the cell-activating properties of C5a (neutrophil chemotaxis, activation of neutrophil leukotrienes and mast cell degranulation), but there is loss of vasoconstrictive properties.

Mechanism of action

The mechanism for the diverse actions of arginine on the immune system are not fully understood. Nonetheless several hypothesis exist. Arginine via its secretagogue effects promotes growth hormone and prolactin release from the pituitary, and insulin and glucagon release from the pancreas. Convincing *in vivo* and *in vitro* evidence suggests an immunopermissive role for prolactin. Hypophysectomized rats fail to mount an adequate immune response to antigenic challenge, a failure reversed by giving them prolactin or growth hormone. Prolactin-like receptors have been identified on the surface of T cells, as has the production of a prolactin-like protein by stimulated T cells. It is likely that arginine (*in vivo*) exerts some effect on the immune system via increased pituitary release of prolactin and/or growth hormone. However, hypophysectomized rats supplemented with growth hormone, thyroxine and testosterone do not demonstrate increased immune responses secondary to arginine supplementation. There are no similar data available for the human immune system. The *in vitro* arginine requirement for optimal lymphocyte responses to lectins also suggests a local cellular response to arginine, possibly via the nitric oxide pathway.

It has been postulated that arginine is required as a precursor for polyamines which are necessary for lymphocyte proliferation. This does not explain why many of the *in vivo* immune effects of arginine are replicated by ornithine but not by citrulline, spermine or putrescine (other precursors of polyamine synthesis). Finally, when looking at macrophage function, intracellular NO formation from arginine explains much of their activities. Within the liver (in rodents), activated Kupffer cell secretory function (TNF α , IL-6) but not phagocytosis is enhanced up to twice normal following dietary supplementation with arginine. Again, the exact mechanism of action is not fully understood. Elsewhere within the immune system the arginine NO pathway is responsible for inhibition of neutrophil aggregation and may on the basis of *in vivo* studies be a requirement for T cell mitogenesis. However, the exact mech-

anism by which arginine influences lymphocyte function *in vivo* remains unknown.

Despite insufficient knowledge regarding its mechanism of action, it is clear that arginine has a potent effect on multiple cells and molecules involved in immune responses. In the future it is likely that arginine may be used as a pharmacologic agent in immunocompromised states.

ARTHUS REACTION

Paul G Hellewell, Applied Pharmacology, Imperial College School of Medicine at the National Heart and Lung Institute, London, UK

Adriano G Rossi, Respiratory Medicine Unit, Department of Medicine, Rayne Laboratory, Edinburgh, UK

The Arthus reaction was first described by Maurice Arthus as an acute inflammatory response induced in rabbit skin by a local injection of horse serum in rabbits sensitized by previous injections of the same substance. Although the reaction described originally could have had components of anaphylactic and delayed hypersensitivity responses, the term Arthus reaction best describes the acute response initiated by local deposition of immune complexes and is an example of type III hypersensitivity. Strictly speaking, the Arthus reaction is restricted to the skin and Arthus-like or Arthus-type reactions occur in other organs.

Antibody–antigen complexes are believed to be principal in the inflammatory response associated with a number of diverse diseases which are listed in Table 1. Some of these are well known while others are more obscure and are complications of other dis-

eases (e.g. erythema nodosum leprosum is a serious complication of lepromatous leprosy) or can be adverse reactions to drugs. In the Arthus reaction as originally described, antigen was injected intradermally into sensitized animals and, as antibody diffused from cutaneous microvessels, immune complexes were deposited in and around the vessel wall. Experimentally it is convenient to induce the reaction passively and in reverse, such that antibody is injected intradermally and antigen intravenously – the so-called reversed passive Arthus reaction.

The Arthus reaction can be dissected into three fairly distinct stages: a rapid increase in vascular permeability and extravasation of plasma protein, which is maximal at 1–2 hours, infiltration of leukocytes (initially neutrophils) and hemorrhage which peak in intensity after 4–8 hours. Longer reactions are sometimes associated with necrosis. Experimentally, hemorrhage is the most notable feature of the reaction in transparent tissues such as skin.

Table 1 Diseases and conditions which have features of the Arthus reaction

Systemic lupus erythematosus
Rheumatoid arthritis
Immune glomerulonephritis
Vasculitis
Kawasaki disease
Erythema nodosum leprosum
Inflammatory demyelinating neuropathies
Hypersensitivity pneumonitis
Reaction to immunization with diphtheria toxoid
Drug hypersensitivity

Role of complement

Immune complex-mediated tissue injury is thought to be mediated in the initial stages by activation of primarily the classical pathway of the complement system. In the Arthus reaction the formation of immune complexes in and around the wall of microvessels (Figure 1) results in the activation of complement and the generation of C3a and C5a as well as assembly of the membrane attack complex C5–C9. Depletion of complement (e.g. with cobra

Figure 1 Some of the mechanisms involved in the pathological changes associated with an Arthus reaction. Although considered to be driven primarily by complement components (in particular C5a), recent studies suggest that the mast cell Fc receptor plays a crucial role (see text for details). Evidence that amines, PAF and LTB₄ contribute to the edema formation and neutrophil accumulation has been obtained from pharmacological studies. A similar approach (using neutralizing antibodies) has demonstrated a role for the cytokines and chemokines listed.

venom factor) reduces the magnitude of the Arthus reaction and has led to the idea that C5a plays a key role in orchestrating the early stages of the reaction. Thus, generation of C5a could act on mast cells to release bioactive amines which increase vascular permeability and C5a itself increases permeability by a mechanism that depends on circulating neutrophils. This would supply more plasma proteins, including complement components, leading to further C5a generation. In support of this idea, both antibodies to C5a and soluble CR1, which inhibits the generation of C5a, provide partial protection against immune complex-induced lung and skin inflammation in animal models. However, this concept has been challenged recently by studies in mice genetically deficient in complement components C3, C4 or C5. In these animals the Arthus reaction is indistinguishable from that in wild-type controls, suggesting that complement is not required.

Role of blood elements and adhesion molecules

One of the characteristic features of the reaction is the accumulation of neutrophils. Experimentally this peaks 4–8 hours after initiating the reaction and an early observation was that edema formation and

hemorrhage in the Arthus reaction could be suppressed by depletion of circulating neutrophils. Similar findings have been made using monoclonal antibodies directed against neutrophil β_2 -integrins and endothelial ICAM-1, which prevent neutrophil recruitment to sites of Arthus reactions, presumably by preventing firm adhesion and migration. Neutrophils contribute to inflammatory changes in the Arthus reaction in several ways: neutrophil-dependent edema formation induced by C5a; neutrophil-derived proteases which could cleave C5 in tissue fluid leading to the generation of C5a; neutrophil proteases such as elastase which could lead to tissue destruction and hemorrhage; neutrophil production of lipid mediators (such as platelet-activating factor (PAF) and leukotriene B₄ (LTB₄)) and chemokines (e.g. interleukin-8, IL-8).

Arthus reactions are also suppressed by reagents that interfere with selectin function, for example an anti-E-selectin monoclonal antibody, which reduce neutrophil accumulation and the attendant pathological changes. This has been attributed to the capacity of selectins to mediate neutrophil rolling, the first stage in the process of leukocyte recruitment. An unexpected finding was the ability of a monoclonal antibody against the leukocyte β_1 -integrin VLA-4 to decrease neutrophil accumulation in

immune complex-induced lung inflammation. As neutrophils do not express VLA-4, the protective effect of the antibody might be due to suppression of macrophage function.

Platelet depletion also reduces neutrophil accumulation in the Arthus reaction. The reason for this is not entirely clear but platelets are suggested to facilitate efficient recruitment of neutrophils into tissues, perhaps via lipid mediator interactions and P-selectin-mediated adhesion.

Mediators involved in the Arthus reaction

A list of inflammatory mediators demonstrated (using a pharmacological approach) to have a role in the pathology of the Arthus reaction is given in Table 2. Biogenic amines (histamine and 5-hydroxytryptamine) released from mast cells, usually in response to the anaphylatoxins C3a and C5a, can increase vascular permeability, although this action is greatest in rodents. Antagonists of these amines have no effect on neutrophil recruitment and hemorrhage. A role for PAF in the Arthus reaction was discovered almost a decade ago and it appears to be an important mediator of plasma leakage. The site of deposition of immune complexes may be important in this regard; in the Arthus reaction neutrophil phagocytosis of immune complexes in the vessel wall releases PAF adjacent to endothelial cells leading to plasma leakage. In contrast, phagocytosis of immune complexes away from the vessel wall does not reveal a role for PAF. The same consideration may apply for LTB₄ because specific receptor antagonists reduce edema formation in an Arthus reaction. Vasodilator prostaglandins (e.g. PGE₂, prostacyclin) produced in the Arthus reaction may modulate edema formation and neutrophil accumulation by augmenting the blood supply; this increases hydrostatic pressure in postcapillary venules and increases the delivery of neutrophils to the tissue.

Of the cytokines, IL-1 is involved in the edema formation, neutrophil accumulation and hemorrhage

in the Arthus reaction and immune complex-induced lung injury. In contrast, tumor necrosis factor α (TNF α) appears to have a more important role in the lung as a number of TNF α inhibitors have no effect on Arthus reactions in skin. The source of these cytokines is speculated to be macrophages which are stimulated by immune complexes. Macrophages are also likely to be one of the sources of chemokines, including IL-8 and macrophage-inflammatory protein 1 α (MIP-1 α), which appear to play a role in the Arthus reaction. However, other cells, including endothelial cells, fibroblasts and even neutrophils themselves, could contribute to production of these mediators.

Other neutrophil-derived factors that contribute to the pathological changes in the Arthus reaction include proteases, particularly elastase which may cleave C5 but also destroys tissue and leads to hemorrhage. Indeed, an elastase inhibitor prevents immune complex-induced hemorrhage in the lung. Nitric oxide (NO) can enhance blood flow and exacerbate the Arthus reaction in a similar manner to PGE₂. Moreover, on interaction with superoxide anion, NO forms the highly reactive peroxynitrite anion (ONOO⁻), which in turn can be protonated to form the tissue damaging hydroxyl radical.

Recent advances in mechanisms underlying the Arthus reaction

As discussed above, recent data suggest that in the mouse the presence of an intact complement system is neither necessary nor sufficient to trigger or propagate an Arthus reaction. This is a surprising finding given that antibodies to C5a are effective at attenuating the reaction in rat and rabbits, and treatment with an anti-C5 mAb for 6 months prevents the spontaneous development of an autoimmune syndrome with features of systemic lupus erythematosus (SLE) in NZB/W mice. In addition, a soluble form of the complement regulatory protein CD46 (membrane cofactor protein), which inhibits complement activation *in vitro*, reduces inflammatory cell influx and edema formation in the Arthus reaction. In the same model, soluble CD35 (CR1) and CD55 (decay-accelerating factor) were also effective as anti-inflammatory agents.

An alternative mechanism has been proposed based on the greatly diminished capacity of mice deficient in the γ subunit of Fc receptors to develop Arthus reactions. Mast cell reconstitution of the mast cell-deficient mouse strain W/W^v reveals that Fc γ RIII on this cell is responsible for triggering the inflammatory response in the Arthus reaction. Other Fc γ RIII-expressing resident tissue cells (macrophages

Table 2 Mediators demonstrated to be involved in the Arthus reaction

Class	Examples
Lipid-derived	PAF, LTB ₄ , prostaglandins
Amines	Histamine, serotonin
Complement-derived	C5a
Cytokines	TNF α , IL-1
Chemokines	IL-8, MCP-1, MIP-1 α
Others	Nitric oxide

and Langerhans cells) and neutrophils could be involved in later stages of the reaction. Similarly, Fc γ RII is involved in aspects of the Arthus reaction. A soluble form inhibits hemorrhage and perivascular neutrophil recruitment; this may be related to suppression of neutrophil activation *in vivo*.

Although much progress has been made in understanding the physiological and cellular mechanisms underlying the Arthus reaction, clearly much has still to be elucidated concerning the relevant inflammatory and hemorrhagic response process to be targeted clinically.

The organism and its antigens

Ascaris lumbricoides is among the most widespread and common of all pathogens of humans, infecting over 1.3 billion people. It is a nematode, or 'round-worm', and can arguably present the human host with a greater burden of foreign biological material than does any other parasite. Sexually-producing adult worms develop in the intestine to a maximum size of about 400 mm long by 6 mm thick, and females release eggs at the rate of 200 000 per day. These take about 2–3 weeks to embryonate and produce the infective larvae. Following ingestion, the larvae emerge from the egg, invade the mucosa, migrate to the lungs via the liver, break out into the alveoli, move up the trachea and are swallowed. Upon re-entry to the intestine, they develop to mature adult worms, mate, and eggs usually begin to be released in the feces by about 60–70 days of infection.

It has often been written that the vast majority of ascariasis cases are symptomless, but it is becoming clear that chronic malabsorption and malnutrition can result, and even single worms can prove lethal by penetrating the bile or pancreatic ducts. Rupture and/or blockage of the intestine by the sheer mass of worms is estimated to kill about 20 000 children a year, but this is almost certainly a gross underestimate. Treatment by anthelmintics is effective but parasite infections can return to pretreatment levels within 1 year because of contamination of the environment with the highly persistent eggs. There is, therefore, little evidence for the acquisition of a sterile immunity to the parasite in humans, although certain individuals appear to remain consistently uninfected. A characteristic of most helminthiases, including ascariasis, is that the parasite population is overdispersed within a host population. That is, most of the parasites are present in a small proportion of potential hosts, and the majority of people are parasite-free or have only small burdens. Among infected individuals, children tend to suffer infections of greater intensity than do those in older age groups. Recent genetic studies on the parasites have shown that the closely related parasite of pigs, *A. suum*, probably does not reach maturity in humans, but exposure to it might nevertheless influence the immune response to *A. lumbricoides*.

The first clinical signs of infection are associated

with the pulmonary phase and include pneumonitis, cough, dyspnea, substernal pain and sometimes a blood-stained sputum. This is known as the Löfller syndrome and has some of the characteristics of an immediate-type hypersensitivity response. There can be a dense pulmonary infiltrate at this time, and a rising eosinophilia. Pulmonary hypersensitivity can cause significant mortality among children in arid regions where high-level seasonal transmission occurs. The intestinal phase is associated with digestive disorders, nausea and colic. Villous atrophy has been demonstrated in infected children and pigs, and is probably immune-associated.

Until recently, work on the antigens of *Ascaris* has been confined to somatic materials of the parasite. These have been shown to be rich in the phosphorylcholine hapten, and antibody responses to it are a major part of the response to infection in mice. The determinant is found internally and is not thought to be exposed on the parasite surface. *Ascaris* is renowned among laboratory workers for its content of allergens, and proteinaceous allergens ranging between 14.4 and 360 kDa have been described. A nonspecific mast cell-degranulating factor of about 9 kDa has also been described from *Ascaris*. The extent to which these substances contribute to pathology is not clear, but there is one report of lethal intestinal anaphylaxis following chemotherapy for ascariasis, and it is likely that parasite allergens contribute to pulmonary hypersensitivity.

It is now clear, however, that antigens released by the tissue-invasive larvae of the parasite (usually termed 'excretory/secretory' (ES) products) are potentially immunogenic and that the set of (glyco) proteins of which they are comprised changes radically during the migration from intestine to lungs. The larvae also release several proteinases, the biochemical activity of which are inhibitable by antibody elicited by the infection. ES products contain components ranging from 14 to 410 kDa, the 14 kDa component also being found in abundance internal to the worm, and is a potent allergen named ABA-1. This protein is now known to be a fatty acid and retinoid-binding protein which appears to have no homolog in vertebrates, and has highly unusual binding characteristics. It is thought to be a four-bundle α -helix protein with its binding site in its core (Figure 1). ABA-1 is a member of the nematode

Figure 1 Model of the ABA-1 allergen of *Ascaris*, showing the proposed four α -helix bundle structure. The protein is known to form dimers and the position of putative external hydrophobic patches on helices 1 and 2, which may act as the subunit interface, are shown as black rectangles. (Courtesy of Dr A Brass, University of Manchester, UK.)

polyprotein antigens/allergens which appear to be produced by all nematodes as a polyprotein that is cleaved by proteinases during post-translational processing into multiple copies of the active allergen protein.

Immune response of the host

Infected humans produce strong immunoglobulin G (IgG) and IgE antibodies against the parasite, but most people respond only to a subset of parasite components. For instance, only about one in five infected people appear to respond to the ABA-1 antigen/allergen. This heterogeneity has been modeled in laboratory rodents in which the immune repertoire to *Ascaris* antigens is restricted by the class II region of the major histocompatibility complex. A surprising feature of the restriction is that it applies to whole molecules as large as 220 kDa. A similar genetic restriction probably explains the limited repertoire seen in humans, but heterogeneity in recognition of individual parasite components might mean that people will vary in the specificity of their hypersensitivity reactions to *Ascaris*. Moreover, there is growing evidence that the IgE response is protective

in ascariasis, as is thought to be the case in some other helminth infections. Experiments in mice have shown that the immune response in *Ascaris* infection is dominated by T_H2 cells, which presumably explains the high IgE, mastocytosis and eosinophilia of the infections. In experimental infections in mice with other species of intestinal nematode, the T_H2 response is crucial to the immune elimination of the parasites.

Evasive strategies by the organism

Anything written on evasion strategies in nematodiasis remains speculative. The parasite alters its surface and secreted antigens during its tissue migrations, and it has been suggested that this functions to keep the parasite ahead of the immune response. This would not, however, be compatible with the continuous recruitment of parasites known to occur in infected humans. The larvae secrete proteinases which could cleave bound antibody and/or complement. Parasitic nematodes commonly secrete antioxidants, such as superoxide dismutase, but this has not been examined for *Ascaris*. If, like the related nematode *Toxocara canis*, *Ascaris* has a surface that rapidly sheds antigens, then continuous loss of bound antibody, complement and/or cells would provide an immune evasion mechanism. It also might simply be that it is not possible for the immune system to deal with a rapidly migrating multicellular parasite. The intestinal stage of *Ascaris* is thought to live for at least 1 year, and there appear to be successive waves of recruitment. It is not known how these worms evade the immune response, although it is known from experimental models that some species of gastrointestinal nematodes are able to suppress local and sometimes systemic immune responses. Another possibility is that T cell tolerance to these long-term occupants of the gut is generated.

Vaccines

There is no vaccine, and no immediate prospect of one. ES antigens are known to be partially protective in rodents and pigs, and are therefore attracting attention. It has become conventional that parasite surface antigens be investigated, but their activity as protective antigens has not been examined for *Ascaris*. Only one vaccine against any nematode parasite is currently available, the irradiation-attenuated vaccine against the lungworm of cattle and sheep, *Dictyocaulus viviparus* and *Dictyocaulus filariae*. Ultraviolet-irradiated larvae of *Ascaris* confer partial resistance in pigs, but such a preparation would probably not be acceptable for human or vet-

erinary use because of the associated pathology, particularly in the liver. The design of a vaccine against *Ascaris* (as with all pathogens) comprising recombinant proteins would have to take into account the genetic restriction of the immune repertoire. Some new generation vaccines are thought to circumvent this restriction, but this has not yet been found to be the case for nematode antigens. Likewise, the importance of IgE antibody to protection will need to be considered, although immunization regimens designed to generate an IgE response may be necessary; they would need to be designed to avoid unacceptable hypersensitivity responses in vaccinated subjects who may already have been sensitized by infection.

ASTHMA

David M Essayan and **Lawrence M Lichtenstein**, Division of Clinical Immunology, Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

Asthma is a disease of the lungs affecting both children and adults and characterized by: 1) airway obstruction that is partially or completely reversible, 2) airway inflammation, and 3) airway hyperresponsiveness. A persistent rise in disease prevalence, hospitalizations due to disease exacerbation, and disease mortality over the last two decades underscores the importance of an increased understanding of disease pathogenesis and the development of improved therapeutic agents. This entry summarizes our current understanding of this disease entity.

Epidemiology

There is a close concordance between asthma, allergic rhinitis and atopic dermatitis; the presence of one of these entities increases the relative risk of the other two by 3- to 30-fold over the lifetime of the subject. All three of these diseases are associated with high levels of nonspecific and antigen-specific serum immunoglobulin E (IgE).

The worldwide prevalence of asthma in childhood ranges from approximately 1.4 to 11.4%, but varies widely by racial and geographic factors and ascertainment methods. The overall prevalence of asthma is approximately equal in industrialized and nonindustrialized nations; however, prevalence tends to be less in rural than in urbanized communities. Moreover, children emigrating from rural to urbanized areas tend to assume the relative risk associated with their new environment, implicating exposure to extrinsic agents in disease pathogenesis. In developed countries, asthma is the second leading cause of hospitalization in children. Finally, greater than 70% of bronchial hyperresponsiveness (BHR) in adults and greater than 85% of BHR in children is associated with IgE sensitivity to various, predominantly inhaled, allergens.

A strong genetic influence on the development of asthma has also been described in studies of mono- and dizygotic twins. Vertical transmission studies show a 25–35% relative risk of asthma conveyed to each child by each affected parent. Finally, a

synthesis of data from various linkage studies in affected kindred have shown associations of the asthma phenotype to microsatellite markers on chromosomes 4, 6, 7, 11, 13 and 16, with more specific mapping to 11q13 (FceR1 β), 5q31 (IL-4, -5 and -13 gene cluster), 6p21 (HLA-DR), 14q11.2 (T cell receptor α/δ chains) and 12q15. Thus, our understanding of disease pathogenesis must take into consideration the multifactorial nature of this clinical entity.

Pathogenesis

The key initiating event in the pathogenesis of asthma is currently felt to be inflammation of the conducting airways. T lymphocyte activation is suggested by increased surface expression of CD25, CD45, HLA-DR and VLA-1 on lymphocytes from bronchoalveolar lavage (BAL) and bronchial biopsy specimens of asthmatic subjects. Moreover, expression of interleukin-4 (IL-4) and IL-5 but not interferon γ (IFN γ), in a pattern consistent with a T_H2 response, has been shown in asthmatic subjects; this expression is greater in symptomatic subjects, increased after allergen challenge, positively correlated with asthma symptoms, and negatively correlated to FEV₁ (forced expiratory volume in 1 second). Early activation of pulmonary mast cells is suggested by elevations of both histamine and tryptase in BAL samples immediately following allergen challenge. IgE-dependent activation of mast cells results in the generation of sulfidopeptide leukotrienes that contribute to mucus hypersecretion, increased microvascular permeability and smooth muscle contraction. The participation of tryptase in neuropeptide metabolism may further contribute to neuronally mediated increases in airway smooth muscle tone. The late inflammatory response is associated with a marked

influx of eosinophils and basophils into the asthmatic airway. Eosinophil degranulation is suggested by increases in major basic protein, eosinophil peroxidase, and eosinophil cationic protein in asthmatic airways. These highly toxic substances may promote BHR through direct damage to airway epithelium, resulting in exposure of mast cells and nerve endings. Activation of basophils recruited to these sites of inflammation result in both the generation of mediators of bronchoconstriction and mucus hypersecretion and the elaboration of proinflammatory cytokines such as IL-4 and IL-13. Selective and coordinated recruitment of these various effector cell types may be achieved through the upregulation of specific members of the integrin and selectin superfamilies of cellular adhesion molecules and the elaboration of specific cellular chemoattractants (Figure 1).

The pathology of asthma reflects these basic principles of allergic inflammation. Those airways most affected in asthmatics are the large and medium conducting airways. Classic changes seen on biopsy of severe asthmatic subjects, as well as postmortem examination of subjects suffering fatal asthma, include vascular congestion, mucosal edema with exudation of fluid and proteins from the microvasculature, and infiltration of inflammatory cells into interstitial tissue. Mucus hypersecretion with disruption of pulmonary epithelial cells results in luminal obstruction. Chronic inflammation may also result in airway remodeling with thickening and fibrosis in the region of the basement membrane. Curschman spirals (expectorated casts of inflamed airways), Creola bodies (compact clusters of sloughed epithelial cells), and Charcot-Leyden crystals (condensed eosinophil granular proteins) are considered classic findings in severe asthma. Squamous metaplasia may occur as a response to epithelial disruption. The functional

Figure 1 The pathogenesis of asthma.

consequences of these pathological changes include early airway closure with distal air trapping and increased residual volume, reduced FEV₁ values, and abnormal gas distribution and exchange. Increased airway resistance and tidal volumes closer to inspiratory plateau contribute to an increased work of breathing that is only partially compensated by the use of accessory muscles for respiration. Finally, defects in smooth muscle relaxation may contribute to the pulmonary mechanical dysfunction characteristic of asthma.

Clinical presentation

Asthma may present acutely or as a chronic pulmonary disease. Symptoms of acute asthma include shortness of breath, chest tightness, wheezing and cough, often productive of clear or slightly colored sputum. When present, chest pain is usually musculoskeletal in origin. Audible wheezing may not be present in mild asthma, but may be elicited by forced expiratory maneuvers. Increased diurnal variations in pulmonary function are often associated with nocturnal exacerbations. Triggers for worsening asthma include cold air exposure, exercise, viral respiratory infections, sinusitis, gastroesophageal reflux, exposure to seasonal or perennial inhalant allergens, and exposure to inhaled irritants such as cigarette smoke. Seasonal variations in asthma severity often correlate with seasonal allergen exposure. Finally, a number of medications, including β adrenergic blockers and nonsteroidal anti-inflammatory agents, as well as sulfite preservatives, may exacerbate asthma in susceptible subjects. A correlation of total suspended particles and levels of various air pollutants to exacerbation rates for asthma has been reported.

Physical signs of acute asthma include tachypnea, tachycardia, pulsus paradoxicus, hyperinflation of the chest, audible wheezing, and the use of accessory muscles of respiration. Chest roentgenogram may show flattening of the diaphragms bilaterally and increased anteroposterior dimension. Pulmonary function studies reveal an obstructive pattern which may be partially or completely reversed by the administration of β -adrenergic agonists. Diurnal variations in peak expiratory flow rate greater than 20% are highly suggestive of asthma. Bronchoprovocation with a variety of agents, including methacholine and histamine, may identify subjects with BHR. However, it should be noted that the perception of asthma by an affected subject may not correlate to the degree of pulmonary dysfunction due to an impaired sensitivity to hypoxia and hypercarbia.

The differential diagnosis of asthma includes mechanical obstruction of the airway (extrathoracic

and intrathoracic), laryngeal dysfunction, chronic obstructive pulmonary disease, cardiac dysfunction, pulmonary embolism, pulmonary infiltrates and eosinophilia (PIE syndrome), cough due to drugs (angiotensin-converting enzyme ACE inhibitors), and carcinoid tumors. The majority of these entities may be readily differentiated from asthma on the basis of clinical presentation, physical examination, roentgenographic studies and pulmonary function testing.

Treatment

Nonpharmacologic

Optimal management for asthma of any stage should include a number of nonpharmacologic measures. Paramount among these is education of the patient and family concerning basic issues of disease pathogenesis, mechanisms of action of medications, and the proper technique for the use of metered-dose inhalers. Avoidance of allergic and irritant triggers of asthma, particularly indoor allergens (dust mite, animal danders, cockroach and mold) and indoor irritants (cigarette smoke, colognes) should be encouraged. Finally, every patient should be instructed in the proper use of step care for asthma exacerbations due to exposures and viral illnesses, with the objective of reducing the necessity for acute and subacute care (Figure 2).

Pharmacologic

Nonacute asthma may be classified as mild, moderate or severe on the basis of clinical parameters. Mild asthma is defined as exacerbations of cough and wheezing less than twice a week with few clinical signs or symptoms between exacerbations, good exercise tolerance, nocturnal symptoms less than

Figure 2 The beneficial effects of anti-inflammatory therapy on frequency, duration and severity of exacerbations in asthma.

twice a month, and a resting peak expiratory flow rate (PEFR) of >80% of predicted with less than 20% diurnal variability. Moderate asthma is defined as exacerbations more than twice a week, resulting in urgent care treatment less than three times a year, with periods of minimal symptoms between exacerbations; exercise tolerance in these patients is slightly diminished, nocturnal symptoms may be present 2–3 times a week, and resting PEFR may be 60–80% of predicted with diurnal variability of 20–30%. Severe asthma is characterized by daily symptoms with frequent exacerbations and frequent utilization of urgent care facilities or a history of respiratory failure. Patients with severe asthma have poor exercise tolerance, frequent nocturnal symptoms, resting PEFR <60% of predicted with diurnal variability >30%. Risk factors for fatal asthma include hospital admission for severe asthma within the preceding year, a history of respiratory failure with hypercarbia due to asthma, and a history of barotrauma. Pharmacologic therapy should be targeted to clinical stage, as summarized in Table 1. A synthesis of available studies suggests that immunotherapy for inhalant allergens reduces BHR, frequency and/or severity of exacerbations, and medication usage in all three clinical stages of chronic asthma. Leukotriene antagonists may be useful for all stages of asthma, and particularly effective for aspirin sensitive asthmatics. Agents considered investigational at this time for the treatment of severe asthma include methotrexate, gold, macrolides and cyclosporine.

The treatment of acute asthma should focus on intensification of pharmacologic therapies and maintenance of respiratory function with the use of ventilatory support and neuromuscular paralysis as necessary. Therapeutic BAL may be useful in selected patients. Mucolytic agents and iodides are contraindicated.

Special considerations

Occupational asthma

Approximately 2% of all asthma is related to occupational exposures. A large and growing list of agents may precipitate this syndrome, including vegetable materials, chemicals, animal materials, metals and pharmaceuticals. While the high molecular weight compounds are complete antigens that elicit IgE synthesis, many of the low molecular weight compounds are haptens, creating a complete antigen only when bound to carrier proteins. There is often a latency period between the onset of exposure and the development of clinical disease. Symptoms tend to be worse on work days and better on weekends and holidays. Bronchoprovocation testing with the specific agent may confirm the diagnosis. Subjects with long exposure histories may suffer chronic pulmonary dysfunction despite removal from the environment.

Asthma during pregnancy

Poorly controlled asthma poses significant risks to both mother and fetus. The primary goals of asthma therapy during pregnancy are stabilization of disease with prevention of exacerbations and rapid, early intervention for acute exacerbations should they occur. Intensification of nonpharmacologic therapies is indicated: risk/benefit analysis suggests a positive profile for most asthma medications, particularly the inhaled medications.

ATAXIA TELANGIECTASIA

Richard A Gatti, Department of Pathology, UCLA School of Medicine, Los Angeles, California, USA

Ataxia telangiectasia (AT) is a rare (1:40 000 live births) pleiotropic disorder whose various phenotypic manifestations include a progressive cerebellar ataxia, ocular apraxia, and oculocutaneous telangiectasia (Figure 1). Almost all patients have an elevated serum α -fetoprotein (AFP). Translocations involving chromosomes 7 and 14 are characteristic. About half of the patients have a moderate to severe immunodeficiency, involving both B and T cell compartments. One-third of patients develop cancer, usually lymphoid. Because these patients are hypersensitive to ionizing radiation and are cancer susceptible, they are in grave danger of being overtreated with conventional doses of radiation therapy. The disease is inherited as an autosomal recessive trait. Despite previous work describing four complementation groups, only a single AT gene exists, ATM (AT, mutated). Most patients are compound heterozygotes, i.e. they inherit a different mutation from each parent. The function of the ATM gene is presently unknown; however, much evidence suggests that one of its primary roles is to sense double-stranded DNA breaks and alert the cell, via signal transduction pathways upstream of p53, not to enter the S (synthesis) phase of the cell cycle until the DNA damage has been repaired. No doubt the ATM gene product will have other roles as well. AT cells have G₁, S, and G₂/M checkpoint defects. All DNA repair

mechanisms that have been tested in AT patients have been normal.

Neuropathology

The most apparent characteristic of the AT syndrome is the ataxia. Shortly after learning to walk, AT children begin to stagger; by 10 years of age, they are confined to a wheelchair for the remainder of their lives. The most obvious lesion in the central nervous system at postmortem examination is a paucity of Purkinje cells in the cerebellum. These cells are present in normal numbers at birth but degenerate progressively. Purkinje cell migration and arborization are also abnormal, lesions that would have had to have been expressed during the third trimester of pregnancy, long before symptoms appear. It is not known whether the Purkinje cell degeneration is central or results from anterograde or retrograde degeneration.

Radiosensitivity

Radiation therapists have observed that when AT patients with cancer are treated with conventional doses of ionizing radiation, they develop sequelae characteristic of much higher dosages. The radiosensitivity can be demonstrated *in vitro* as well, usually

Figure 1 The AT syndrome.

by 'radioresistant DNA synthesis' or by colony survival efficiency following radiation. In the laboratory, carriers are intermediate in radiosensitivity between homozygotes and normals. AT cells are sensitive not only to ionizing radiation but to a variety of radiomimetic agents as well. Testing for radiation hypersensitivity can be used to confirm the diagnosis; however, few laboratories test clinical specimens. Our laboratory uses an Epstein-Barr virus (EBV)-transformed lymphoblastoid cell line (LCL) to measure *in vitro* radiosensitivity (Figure 2).

Figure 2 Colony survival assay (CSA) measures radiosensitivity of LCLs to 1 Gy on patients with AT, AT heterozygotes, and normals. Also included are results on patients with NBS (V₁), BBS (V₂) and AT_F (V₃).

Heterozygotes cannot be distinguished by this method under the conditions used.

Cancer susceptibility

During the shortened lifetimes of AT homozygotes, 38% develop a malignancy, usually lymphoid. This represents a 61-fold and 184-fold increase in Euro-American and Afro-American patients, respectively. About half of the malignancies observed are lymphomas, usually of the B cell type. Leukemias account for another quarter of the malignancies. These are usually T cell leukemias. Young AT patients develop a less aggressive T cell leukemia than older patients, who develop a prolymphocytic leukemia (T-PLL); the latter was formerly described as T-CLL because the cells histologically resemble those of chronic lymphocytic leukemia. However, the T-PLL cells are T cells. Myeloid leukemias have not been described in AT patients. AT heterozygotes are also cancer prone, although not to the extent that homozygotes are. Breast cancer was observed to be five-fold higher among heterozygotes in US families. Based on this observation and an estimated carrier frequency of 1%, it has been postulated that between 8 and 18% of all breast cancer patients may be AT heterozygotes. Despite this prediction, recent genetic screening of breast cancer patients for ATM mutations has failed to reveal increased numbers of AT heterozygotes. Further studies are in progress to

answer this question. Meanwhile, ATM knockout mice all die with malignant thymic lymphomas, closely mimicking the cancer susceptibility of AT patients.

Chromosomal instability

Almost all AT patients have translocations involving the T cell receptor gene complexes at 14q11, 7q35 or 7p14, making up about 10% of metaphases counted. AT heterozygotes have similar translocations in about 1% of their T cells. Normals also have such translocations in about 0.1% of their T cells. Chromosomal aberrations in fibroblasts and amniocytes of AT patients are random and do not show the characteristic translocations. The T-PLL leukemia of AT patients is frequently associated with translocations or inversions involving the same sites described above. These translocations juxtapose part of a T cell receptor gene to a site just proximal to either the TCL-1 (T cell leukemia 1) gene at 14q32 or the c6.1B/MTCP-1 (mature T cell proliferation 1) gene at Xq28. Other factors must also be necessary for leukemia to develop since some AT patients have these clonal expansions in 100% of their T cells for many years and yet do not have leukemia. The frequencies of both mitotic and meiotic recombination are increased in AT cells, as is intrachromosomal recombination. Gametogenesis may be abnormal. ATM knockout mice have gonadal streaks, female animals do not ovulate, and male animals are sterile. Despite this, most AT patients reach normal sexual maturity, with normal menstrual cycles in females, and the ability to produce sperm in at least some males.

Immunodeficiency

At postmortem examination, virtually every AT homozygote has had a small embryonic-like thymus. No single uniform immunological abnormality has been found in AT patients. Indeed, even affected siblings often have different degrees of immunodeficiency. IgA and IgG2 deficiencies have been described in 60% and 80% of patients, respectively. Occasional AT patients have hyper-IgM, with hyperviscosity of blood and splenomegaly. T cell levels are normal to slightly reduced in AT patients. A suggestion that a $\gamma\delta$ T cell subset is increased in AT patients has not been generally confirmed. CD4⁺/CD45RA⁺ (naive) T cells are decreased in some patients. Responses to mitogens, antigens and allogeneic cells are usually slightly reduced, although a few patients have profound deficiencies of T cell responses. T cells show abnormally fast capping of FITC-labelled con-

canavalin A. Natural killer (NK) cell activity and NK cell levels have been described as normal, decreased, or increased in various studies. Some of these discrepancies may reflect transient immunological changes during infections. Unlike all other immunodeficiency symptoms, opportunistic infections are not seen in AT patients.

The ATM gene and mutations

The AT gene was isolated in 1995, culminating a 14-year positional cloning effort by an international consortium of investigators. The ATM gene and gene products are very large: 3056 amino acids, 350 kDa protein, and a 13 kb transcript that may be alternatively spliced in some tissues. The ATM gene is expressed in all tissues tested. The gene has 66 exons, each of about 100–300 base pairs in length; these are spread over about 150 kb of genomic DNA at chromosome 11q23.1. Eighty-five per cent of mutations result in a shortened (truncated) protein. Since the gene has a phosphatidylinositol 3-kinase domain at the 3' end, truncated proteins probably will be lacking this important functional domain. Many of these truncations result from deletions of 1, 2 and 3 exons because of mutations at splice sites. About 200 mutations have been characterized thus far (Figure 3); only two potential hotspots can be appreciated at exons 54 and 16. The rest of the mutations are found across the entire gene, making it difficult to identify each patient's mutations without a great deal of screening of the gene. The most useful screening techniques thus far have been protein truncation testing (PTT), single-strand conformational analysis (SSCA), heteroduplex analysis (HA), conformation-sensitive gel electrophoresis (CSGE), RNAase cleavage assay (RCA), and restriction endonuclease fingerprinting (REF). Each of these must then be followed by DNA sequencing to identify the actual site of the mutation. A few common mutations have been identified and can be tested easily among Amish, Central-Southern Italians, Moroccan Jews, Midland English, Norwegians, Costa Ricans and Polish.

Related syndromes

Several related syndromes overlap with AT. Nijmegen breakage syndrome (NBS) shares t(7;14) translocations, radiosensitivity, immunodeficiency and cancer susceptibility with AT but these patients do not have ataxia, telangiectasia, nor elevated AFP; NBS patients are microcephalic and mentally retarded. AT patients are usually not mentally retarded. Berlin breakage syndrome is very similar

Figure 3 Spectrum of ~120 ATM mutations based on studies of cDNA from cells of patients from many countries. Mutations seen in related (i.e. shared haplotypes) families are indicated only once (boxes) so as not to bias the distribution.

to NBS but sometimes includes syndactyly or anal stenosis. AT_{Fresno} combines the AT and NBS syndromes. AT_{Fresno} patients have ATM mutations. NBS and BBS families do not link to 11q23.1 and, therefore, are probably caused by mutations at another (AT-related) gene.

Therapy

There is no effective therapy for the progressive ataxia. Spasticity can be controlled in some patients with bromocriptine; however, the safety of this medication has not been established for children under 15 years. Valium has been used to ameliorate chronic jerks and tremors but its effects are short-lived. Vitamin E (α -tocopherol) is sometimes prescribed to minimize nonspecific free-radical damage to tissue, although its efficacy is unproven. Immunotherapy is only indicated for patients with frequent recurring infections. Intravenous gamma globulin is effective in reducing the frequency and severity of infections in such patients. Conventional dosages of radiation therapy and radiomimetic agents are contraindicated and life-threatening.

Physical activities such as swimming and calisthenics maintain muscle tone, prevent fractures and slow the side-effects of long-term confinement to a wheelchair – most notably, contractions of hands and feet. Speech therapy helps articulation and voice volume. Good pulmonary hygiene and regular breathing exercises minimize lung impairment, although there is a bit of evidence that the lungs of AT patients may be anatomically compromised by the disease itself. Parental counselling is of paramount importance in alleviating confusion and anxiety. Bringing members of AT families together periodically as a *de facto* support group is also effective therapy. Prenatal diagnosis is now feasible and is quite accurate, with a turnaround time of 1–2 weeks.

ATOPIC ALLERGY

Glenis Scadding, Royal National Throat, Nose and Ear Hospital, London, UK

Definition

Allergy was originally defined in 1906 by Clemens von Pirquet as 'altered reactivity' to denote the different reaction which occurs on second exposure to an antigen, due to the formation of antibodies, when compared to the first exposure. Used in this way the term covered all immune reactions; however, its use has since become restricted to certain hypersensitivity reactions. The term atopy (from the Greek 'out of place') was introduced by Coca and Cooke in 1923. They had observed that certain disorders, such as asthma, eczema and urticaria, run in families and that affected subjects show positive wheal and flare skin reactions to common inhalant antigens, but lack precipitating antibodies.

Prausnitz and Kustner in 1921 demonstrated the transfer of atopic reactivity to normal skin by means of serum. The serum factor, called 'reagin' was identified as a new class of immunoglobulin, IgE, in the 1960s.

Immunoglobulin

IgE has the usual immunoglobulin structure of two heavy and two light chains and is heavily glycosylated, containing about 12% carbohydrate. There are five domains in the heavy chain, compared to four in IgG1. A part of the Fc region of IgE (C_H3 and

C_H4) is the binding site for high affinity Fcε receptors on mast cells and basophils. This activity is destroyed by heating at 56°C for 30 min; however, antigen binding activity, which resides in the Fab part of the molecule is not heat labile. Serum levels of IgE are far lower than for other immunoglobulins, being measured in nanograms as opposed to milligrams per milliliter. The half-life of IgE in serum is short (2.5 days); once cell bound, this is increased to several weeks.

Individuals produce IgE in response to certain stimuli, such as parasitic worms, but atopic individuals produce it in response to harmless airborne and/or ingested antigens, which are termed allergens. These include grass pollen, animal dander, house dust mite feces, moulds, food antigens and also industrial substances such as toluene di-isocyanate, plicatic acid and platinum salts. Guidelines for allergen nomenclature recommend the use of the first three letters of the genus, plus the initial of the species, followed by a roman numeral which usually reflects the order in which the allergen was isolated. Major allergens are however designated I. Thus the major house dust mite allergen is known as Der p1, the major cat allergen as Fel d1, etc.

Basis of atopy

The incidence of atopy is closely related to the serum IgE concentration, with less than 5% of the

individuals with levels less than 60 iu/ml (1 iu = 2.4 µg) being affected, but over 95% of those with values over 450 iu/ml. There is also an obvious genetic influence, with over 50% of individuals having two allergic parents being atopic, compared with 15% in the normal population. There are several genetic influences determining IgE production: an autosomal dominant gene codes for low IgE levels, HLA-linked genes control IgE and IgG production against specific allergenic proteins (most noticeable for minor determinants when total IgE is low), and HLA-B8 and DRW3 are associated with general immune hyper-responsiveness, possibly via decreased T suppressor activity. Genetic linkage of atopic IgE responses to chromosome 11q13, now observed by several groups, is strongest in maternally derived alleles and may contribute to the maternal inheritance of atopy seen in many studies. The gene for the β chain of the high affinity IgE receptor is a candidate for the chromosome 11q13 effect. A polymorphic variant Leu181/183 was present in 4.5% of the population of Busselton, Western Australia, and when inherited maternally carried a significant risk of atopy and bronchial hyper-responsiveness, but accounted for only a part of the atopy and asthma in that population. Other candidate genes are the TCR α region on chromosome 14 and the interleukin-4 (IL-4) cluster on chromosome 5, both of which show linkage to IgE responses.

Environmental influences are also important: smoking and the use of β -blocking drugs in pregnancy increase the incidence of atopy in offspring. Early contact with highly allergenic proteins (as in cow's milk, eggs, fish, nuts, Der pI, Fel dI) before mucosal protective mechanisms, especially IgA, are fully established appears to contribute to allergy in genetically predisposed infants. Environmental risk factors for seasonal rhinitis include higher social class, being the first-born child and not having to

share a bathroom. These suggest that early infections may have a protective antiallergic effect, possibly by interferon γ production.

The incidence of allergic diseases (hay fever, asthma and eczema) in the population is increasing, possibly caused by increased exposure to indoor allergens, or by the adjuvant effect of atmospheric pollutants such as diesel fumes, or possibly by dietary changes. Disruption of mucosal surfaces, allowing increased antigen entry and IgE production can occur following exposure to pollutants such as sulfur dioxide or during viral infections. Viruses can precipitate allergic symptoms, especially following respiratory syncytial virus infections in childhood.

Type I hypersensitivity

The central mechanism of atopic allergy is type I hypersensitivity (Figure 1). Mucosal contact with allergen results in uptake by an antigen-presenting cell (APC) and presentation in the form of an allergenic peptide held in the groove of the major histocompatibility complex (MHC) class II molecule to a helper T lymphocyte. This then provides help for a previously committed B cell, which is capable of recognizing the antigen, to make IgE antibody.

Factors determining IgE rather than IgG production are not fully understood; however, the nature of the antigen-presenting cells may be relevant. In atopic eczema and allergic rhinitis Langerhans cells which are HLA-DR positive and bear high-affinity IgE receptors have been described. Class switching to IgE is promoted by cytokines IL-4 and IL-13 and is inhibited by interferon γ . In atopics increased levels of T_H2 type T cells producing IL-4 have been described, e.g. in vernal conjunctivitis.

A second signal required for IgE expression is delivered by a soluble fragment of Fc ϵ RII (CD23). This is also upregulated by IL-4. Class switching

Figure 1 Type I hypersensitivity.

with the production of mRNA for IgE has been described within 30 min of allergen contact. Initial IgE production probably takes place in the local lymphoid tissues. Once produced, the IgE is rapidly and avidly bound by its Fc piece to mast cells and basophils, which are then sensitized. Subsequent contact with the same allergen results in cross-linking of IgE molecules by their Fab portion, calcium ion influx, cell degranulation and mediator release.

Certain mediators exist preformed in granules within the cell, others are formed after activation by phospholipase A₂ breakdown of the cell membrane to release arachidonic acid. This is then metabolized by the cyclo-oxygenase or lipoxygenase pathways, depending on the cell type, to produce prostaglandins and thromboxanes, or leukotrienes respectively. Recent research suggests that there is a third phase of cytokine production taking place in the mast cell during the hours after degranulation. This involves *de novo* protein synthesis and results in the generation of several cytokines, including IL-3, IL-4 and IL-5. Storage of IL-4 has also been demonstrated within mast cells and its release can occur on degranulation.

Degranulation of mast cells and basophils can also occur following cross-linking of adjacent membrane-bound IgE molecules by anti-IgE, by anti-idiotype, or by lectins. Fab portions of anti-idiotype could occupy IgE antigen-binding sites without causing cross-linking and degranulation, and can thus theoretically protect against allergen challenge.

Pseudoallergy

Certain substances can affect mast cell membranes directly, allowing Ca²⁺ ion influx and release of gran-

ule contents. These include the anaphylatoxins, C3a and C5a, secretagogues such as calcium ionophore A23187 and mellitin (a component of insect venom) and drugs such as codeine, morphine and synthetic adrenocorticotropin. Physical stimuli such as pressure, heat, cold and sunlight can cause mast cell degranulation in certain individuals.

Late-phase response

The above mechanism accounts for the immediate allergic reaction; however, in many cases inflammation with ingress of many cell types, including eosinophils, further mast cells, basophils, neutrophils and lymphocytes, occurs within hours of allergen contact. The mechanisms for this depend partly on chemotactic factors released by mast cells, but probably more on cytokine production by T lymphocytes (IL-3, IL-5, IL-10, granulocyte-macrophage colony-stimulating factor (GM-CSF)), macrophages (GM-CSF) and endothelial cells (GM-CSF), together with mast cells (IL-2, IL-3, IL-4, IL-5) (Figure 2). This cytokine network provides the basis for clonal amplification of T cells, B cells and inflammatory cells such as mast cells, basophils and eosinophils. Cells passing in nearby blood vessels are recruited to the site of inflammation, becoming attached to the vascular endothelium, via expressed integrin molecules on the cell surface which interact with receptors such as ICAM-1 and iC3b on the vascular endothelium. Expression of integrins and their receptors is upregulated by inflammatory cytokines. The cells then diapedese through the vascular endothelium and migrate down a chemotactic gradient to the site of allergic inflammation.

Figure 2 Some of the pathways leading to the late phase inflammatory reaction which is seen in chronic allergic disease.

Physiological effects

The physiological effects of the mast cell-derived mediators fall into three main groups: spasmogens, activators and chemoattractants. In humans the major vasoactive amine is histamine, which causes vasodilatation, increased capillary permeability and bronchoconstriction. Prostaglandin (PG) D₂, leukotrienes (LTs) C₄ and D₄ and platelet activating factor (PAF) are all newly formed bronchoconstrictors, some of which could be partly responsible for the late phase of the allergic response (see below). PAF also activates platelets, leading to microthrombi and further mediator release. Other activators include tryptase, which is a C3 convertase, and kininogenases, which generate kinins from plasma and tissue kininogens, affecting small blood vessels and leading to inflammation. The chemoattractants include neutrophil chemotactic factor (NCF), eosinophil chemotactic factor of anaphylaxis (ECF-A), which are granule derived, and leukotriene B₄, which is newly formed. These induce a cellular infiltrate which includes neutrophils, eosinophils, basophils and monocytes.

The actual mediators released depend on the cell type involved; for example, basophils do not produce prostaglandin D₂. It is apparent that there are at least two different subpopulations of mast cells in humans, with differences in their morphology and pharmacology.

Clinical effects

The clinical effects of type I hypersensitivity depend upon the site of the reaction: involvement of the nose and/or lungs results in rhinitis and/or asthma; skin involvement causes urticaria. Atopic eczema involves IgE-mediated allergy, although the histology resembles a type IV hypersensitivity reaction. It is possible that an initial type I mechanism causes increased vascular permeability, allowing the influx of lymphocytes. Type I reactions to food can cause immediate reactions involving itching and swelling of the lips, mouth and tongue or may lead to nausea, vomiting and abdominal pain, usually within an hour of ingestion. Where the allergen is injected systemically, as in insect stings and intravenous infusions, and occasionally in a very sensitive subject following ingestion, there may be overwhelming basophil degranulation causing anaphylaxis. This involves massive vasodilatation with a sudden drop in blood pressure and collapse. Other symptoms include bronchospasm, an itchy whealing urticarial rash, gut cramps and diarrhea. Anaphylaxis can prove fatal; the mainstay of treatment is epinephrine (adrenaline), either intramuscular or subcutaneous.

The inflammation of the late phase of the allergic reaction is probably of great importance in chronic allergic disease such as asthma, where the infiltrating eosinophils are thought to damage the bronchial mucosa by means of some of their granule contents: such as major basic protein (MBP) and eosinophilic cationic protein (ECP). Exposure of nerve endings could then contribute, via axonal reflexes, to bronchial hyper-reactivity. In the nose and sinuses the thickened mucosa can act as a predisposing factor to chronic or recurrent infection.

Clinical tests

The onset of the allergic reaction from the time of allergen contact with sensitized mast cells is rapid, taking place within minutes. Skin-prick testing, which is the classical test for allergy, can thus be performed as a rapid diagnostic procedure. Antigen is introduced into the skin, which is examined for the presence of a wheal some 15–20 min later; histamine is used as a positive control, saline as the negative. A positive skin test (wheal 3 mm in diameter larger than saline control) usually correlates with the laboratory test for allergen-specific IgE in blood, the radioallergosorbent test (RAST) and with provocation tests. However, the skin-prick test results must always be interpreted in the light of the patient's history, as IgE reactivity to allergen is not always associated with clinical symptoms. Conversely, a negative skin-prick test can exist where there is only local sensitization in the shock organ; such patients will only give positive results on provocation tests.

Other cells with IgE receptors

Mast cells and basophils possess high affinity ($K_d = 10^{-10}$ M) IgE receptors (FcεRI) which have a six-chain structure (two α, two β, two γ). Recently, other cells, such as Langerhans cells, activated eosinophils, monocytes and macrophages, have also been shown to possess such receptors. Many cells of the immune system bear lower affinity (10^{-6} M) IgE receptors (FcεRII, CD23) of a different structure. This is not a member of the immunoglobulin superfamily but instead shares homology with animal C type lectins such as mannose-binding protein. It is present on B and T lymphocytes, monocytes, alveolar macrophages, eosinophils, platelets and Langerhans cells. Soluble CD23 acts as the second signal for IgE production by B cells. FcεRII-bearing cells increase with allergen exposure. These may have cytotoxic properties when armed with IgE. Similarly, eosinophils and platelets are able to kill *Schistosomula* larvae when sensitized by IgE. This function of parasite killing is

probably the rationale for the existence of IgE and its immune reactions, with atopic disease an unintended byproduct.

Treatment

Treatment of atopic allergic disease falls into three categories: 1) allergen avoidance; 2) pharmacotherapy; and 3) immunotherapy. The major anti-inflammatory drugs used are glucocorticoids, which have a wide spectrum of activity, including reduction of cytokine production and inflammatory cell numbers and activation, a decrease in antigen presentation via a decrease in Langerhans cells in nose and skin, and reduction of mast cell mediator production from arachidonic acid; and sodium cromoglycate, which has multiple effects, including inhibition of mast cell degranulation, sensory nerve function and cytokine secretion. Immunotherapy involves repeated allergen injection; the mechanism of its action may be to induce a T_H1 rather than a T_H2 response locally. Other possibilities such as the use of peptides to produce T cell unresponsiveness, anticytokines and cytokine inhibitors are under investigation.

ATTENUATED ORGANISMS AS VACCINES

Konstantin M Chumakov, Center for Biologics Evaluation and Research, Food and Drug Administration, Maryland, USA

Attenuation is a process of genetic changes leading to a loss of virulence by pathogenic microorganisms while retaining the capacity to induce an immune response in susceptible hosts, resulting in lasting protection from a disease. Attenuation is a part of the natural evolution of pathogenic microorganisms, and is used by man to create 'live' vaccines against infectious diseases (Table 1), in contrast to 'killed' vaccines consisting of inactivated pathogens or their immunogenic subunits. Both types of vaccines have advantages and shortcomings; these will be compared after a brief historical overview and discussion of the general principles behind the process of attenuation. The evolution of pathogens involves several concurrent trends, including immunological drift to escape host defense mechanisms, expansion into new populations (including cross-species adaptation), acquiring new pathogenic factors and properties, and, finally, reduction and loss of pathogenicity (attenuation). While the adaptive value of the former processes is self-evident, as they expand the habitat

of the species, the driving force behind the latter is less apparent. Such 'altruistic' behavior can, perhaps, be explained by the advantages of replicating and spreading without killing a host (which in many cases is a dead end for the microorganism).

Brief history of live vaccines

The oldest example of the use of naturally attenuated organisms for protection against diseases is provided by smallpox. 'Variolation', i.e. deliberate inoculation of susceptible people with virus-containing lymph from pustules of patients with mild forms of the disease, goes back to the early cultures of Africa and Asia. As a result of variolation, patients usually developed the disease with limited lesions, but lasting resistance to smallpox. A few of them, however, had severe disease and some died. By the seventeenth century it was being practised in Europe with the modification of using pustular liquid from cows having a closely related disease, cowpox. In 1796 the British

doctor, Edward Jenner, became aware of this procedure, practised by farmers in southern England, and took the next step by propagating the cowpox through patient-to-patient transfer; he called this procedure 'vaccination' (*L. vacuum*, cow). Thus, he created the first biological and called it a 'vaccine'. This term was later broadened to include all biologicals (live, killed or synthetic) used to induce protective immunity against various pathogenic microorganisms, and to treat noninfectious diseases by stimulating the immune system.

The introduction of smallpox vaccine was responsible for a dramatic reduction of the incidence of smallpox in the nineteenth century and led to its complete eradication in the 1970s. Jenner's work was also important for demonstrating the feasibility of preventing infectious diseases and for identifying, for the first time, a method for achieving artificial attenuation. The 'jennerian' approach, involving the growth of pathogenic microorganisms in a non-human host and the use of closely related animal pathogens, was the basis for the creation of many other live vaccines. Recent examples are experimental vaccines made with bovine and rhesus rotaviruses which protect against human rotaviruses, and bovine paramyxovirus type 3 vaccine which protects man against human parainfluenza.

The next step in the attenuation of microorganisms was taken by Louis Pasteur, who, in 1880, developed a live vaccine against chicken cholera by exposing a bacterial strain of *Pasteurella multocida* to air. The strain could be cultivated *in vitro* and was the first wholly artificial vaccine prepared outside a living organism. In 1881, by extending this approach based on adverse treatment of the microorganism, he proposed the use of a weakened strain of anthrax

bacillus as a vaccine and demonstrated its remarkable effectiveness. In 1885, together with Emile Roux and others, he proposed to immunize against rabies, using a series of successive inoculations of virus preparations with gradually increasing virulence, a procedure similar to variolation but carried out with a vaccine artificially prepared from the virus weakened by air-drying the spinal cords of infected rabbits.

Another method of achieving artificial attenuation of pathogenic organisms by adaptation to growth in culture is exemplified by the BCG (bacille Calmette-Guérin) vaccine. This attenuated strain of *Mycobacterium bovis* was developed in the early twentieth century by the French doctors Albert Calmette and Camille Guérin. They found that the mycobacteria could be grown in culture on potatoes, cooked and supplemented with glycerol and beef bile. After 231 consecutive passages over the course of 13 years, the strain lost its virulence for animals but retained its antigenic properties and was able to stimulate protective immunity against infection with the virulent strain.

In 1935, a combination of growth in nonnatural hosts and in culture was used by Max Theiler to prepare two strains of a live vaccine against yellow fever. The French neurotropic strain (FNS) was attenuated by serial passaging in the brains of mice, and the 17D strain by intermittent passaging in rhesus monkeys and mosquitoes, followed by passaging in whole mouse embryonic tissue cultures, and then in chick embryos. Since the FNS retained a greater degree of virulence, only the 17D strain is currently used in manufacturing the vaccine.

In addition to the above-mentioned principles of attenuation, it was noted that passaging natural viral isolates in cell cultures almost invariably leads to temperature-sensitive (ts) mutations, suggesting that these may be linked to attenuation. This was one of the principles used by Albert Sabin for the creation of oral poliovirus vaccine (OPV) (Figure 1). In many respects OPV is a paradigm for other live viral vaccines and deserves special attention. Sabin noticed that when polioviruses were grown at a low multiplicity of infection, the wild-type strains retained their neurovirulence even after prolonged serial passaging. However, if the virus was passaged at high multiplicity, the degree of neurovirulence dropped. Sabin was also aware of the fact that natural populations of poliovirus consist of a mixture of viral particles with differing 'genetic potentialities'. The term 'quasispecies' is now used to describe this genetic diversity of viral populations. Sabin hypothesized that, while virulent virus particles in a natural mixture replicate to a higher yield and have a replicative advantage in the long run, attenuated particles may

Figure 1 Attenuation of type 3 poliovirus by Albert Sabin.

replicate faster and be selected if replication of the virus is limited in time. Thus he carried out a series of 'rapid' (24 hours) passages in primary monkey kidney cell cultures, nonneuronal in origin, to suppress viral neutropism. The passages were done at 34°C to select for ts mutants. He was able to create strains of all three serotypes of poliovirus with markedly reduced neurovirulence. The strains were then cloned and plaques with the lowest levels of neurovirulence for monkeys were selected for making the vaccine. The attenuated strains had a number of characteristic genetic markers, including a reduced capacity to replicate at high temperatures (rct40) and at a decreased concentration of bicarbonate (d-marker), and, most importantly, very low neurovirulence even when inoculated directly into the central nervous system of monkeys. These strains were highly immunogenic and have become a major tool in the worldwide eradication of the disease, which is anticipated to occur by the year 2000.

Genetic stability

While the attenuated poliovirus strains comprise the basis of a remarkably effective vaccine, they are prone to partial reversion to neurovirulence. Attenuated virus passaged in cell cultures, and the virus excreted by healthy vaccine recipients, were found to have gradually lost their attenuation markers. This required rigorous neurovirulence safety testing during vaccine production. This potential for reversion back to virulence is a general problem inherent in all live vaccines. A similar process occurs in some strains used in the live mumps vaccine, and to a lesser degree in the yellow fever vaccine. A reduction in, and eventual elimination of, this potential for reversion can be accomplished by creating genetically stable vaccine strains using our knowledge of molecular mechanisms of virulence and attenuation.

Molecular basis of attenuation

A reduction in pathogenicity can occur either through the loss of external pathogenic factors (toxins), as is the case with some bacterial vaccines, or by impairing the invasiveness of a pathogen and limiting its access to target organs. In many cases attenuating mutations occur in capsid or envelope proteins of a virus, presumably reducing its affinity for the target cells. Detailed studies of attenuated polioviruses identified a number of mutations that distinguished vaccine viruses from their wild-type progenitor strains. The mutations linked to attenuation were located in genes for both capsid and non-capsid proteins, as well as in the untranslated regulatory regions (UTRs) of the genome. The mutations in a stem-and-loop domain within the internal ribosome entry site (IRES) of the 5'-UTRs were responsible for the attenuation of all three types of poliovirus. These mutations impaired the initiation of viral protein synthesis by decreasing the affinity of viral RNA to cellular initiation factors. This impairment was cell-type specific, as the difference in replicative capacity between attenuated and wild-type strains was much more pronounced in cultures of cells of neuronal origin than in those of nonneuronal cells.

Viruses serially passaged *in vitro* or isolated from recipients of OPV were found to have reverted at some of the attenuated sites (including the one in the IRES) back to the wild-type state. Other mutations were found which boosted the replicative capacity of the attenuated strains *in vitro* but did not contribute to increased neurovirulence in monkeys. While attenuation is generally associated with lowering the replicative capacity, 'weakening' of the virus does not necessarily lead to a loss of pathogenicity. Attenuation is linked to an inability of the virus to replicate in specific target cells (motor neurons in the case of poliovirus), while retaining the ability to replicate in noncritical organs.

Rational vaccine design

Ideally, an attenuated organism would possess the ability to replicate vigorously and induce an immune response, while being completely devoid of virulent properties. Strains with hyperattenuation (reduced vitality) and substantial or unstable residual virulence are unacceptable for use as vaccines. A knowledge of the genetic basis of virulence allows us to target virulence determinants and to create strains lacking the genes required for pathogenicity. Another challenge in vaccine development arises when dealing with viruses that have a very high rate of antigenic drift, e.g. influenza. In this case, standardized tech-

niques for virus attenuation would be desirable in order to prepare vaccines with consistent effectiveness against the new influenza strains that emerge each year. It was found that passaging influenza virus at low temperatures results in attenuation and that the determinants of attenuation are located on the PA, M, PB2, and PB1 genes of the cold-adapted influenza A virus. Genes of influenza viruses are located on separate RNA segments, and so reassortment of the segments bearing the determinants of attenuation with the ones carrying the genes for hemagglutinin and neuraminidase, which are responsible for immunogenicity, resulted in vaccine strains with the desired antigenic structure and a predictably high degree of attenuation.

New genetically engineered bacterial vaccines provide other examples of a rational approach to vaccine design. Hybrids of *Shigella* and *Escherichia coli*, and *Salmonella* and *shigella*, devoid of toxin genes, but expressing important antigens, have been suggested for use in live vaccines. Selective mutagenesis of the cholera toxin gene results in a strain which possesses all of the antigens important for protective immunity, but with much lower pathogenicity.

Recently it has been found that artificial rearrangement of gene order in vesicular stomatitis virus led to strong attenuation of the virus, even though no changes of amino acid sequences was involved, suggesting a new rational way for creating stable vaccine strains of negative-strand RNA viruses.

Attenuated organisms versus killed vaccines

Arguments about the relative advantages of live and killed vaccines are endless and started with the invention of vaccines themselves. Live vaccines are generally less stable than killed vaccines and require freezing during transportation and storage. The possibility of contamination with live adventitious agents, including the unknown ones, is a consideration that is hard to discount. But the greatest shortcoming of live vaccines is their potential for reversion to virulence. Because of this, in the nineteenth century, variolation was considered a felony in England. Modern vaccines, especially the ones created with a knowledge of the molecular basis of virulence, are much safer than the attenuated strains of the past. In addition, sophisticated methods of quality control are now used to ensure the safety of live vaccines.

The advantages of using attenuated organisms as vaccines are numerous. Since they replicate in the body of a vaccinee, the dose of a live vaccine is usually small, which means its cost and potential for antigenic overload and allergization are low. Many

live vaccines can be administered simply by oral or intranasal routes, thus avoiding the hazards of injection. In most cases, vaccination with a live vaccine results in antigenic presentation that closely mimics the natural infection. As a result, immunity is more comprehensive than that induced by killed vaccines, involving both systemic and local factors. For example, immunization with inactivated poliovirus vaccine (IPV) results in high seroconversion rates and high titers of antibodies in the blood of vaccine recipients, but does not create adequate intestinal immunity. Consequently, while the individual immunized with IPV is completely protected from poliomyelitis, the wild-type poliovirus can still replicate in the intestinal tract of the vaccinee and be excreted. Thus IPV cannot break the chain of transmission of wild-type polioviruses, in contrast to OPV, which induces intestinal immunity and results in comprehensive resistance to the poliovirus. OPV stops the circulation of wild-type polioviruses in the human population, and spreads to contacts, thus expanding the reach of immunization. Nonspecific immunity factors such as interferons are produced by live vaccines, which therefore can protect against a wide range of other diseases. For example, OPV has been successfully used to stop outbreaks of diseases caused by other serologically unrelated enteroviruses and has been shown to interfere nonspecifically with infection by other viruses.

Conclusions

As stated earlier, attenuation is a natural part of the coevolution of a host and its microorganisms. As always in symbiotic relationships, both parties benefit. The host provides a substrate for a microorganism's subsistence, which in exchange refrains from causing extensive damage to its host. As an additional payoff, this endosymbiotic microorganisms may help its host to fight off pathogenic microorganisms. This occurs with normal enteric bacterial microflora, and may also be true for naturally attenuated viruses which can temporarily enter into symbiotic relationship with their hosts. A good example of this is the large variety of nonpathogenic enteroviruses (Sabin strains of poliovirus should be regarded as members of this group) that asymptotically infect the intestinal tract and, by stimulating a host's immune system, interfere with a wide range of pathogenic viruses and help the host fight other diseases. Thus, by acting within the framework of existing micro/macroorganism interactions, artificially attenuated viruses and bacteria are a manmade addition to the natural arsenal with which the human body protects itself against diseases.

AUTOANTIBODIES, TESTS FOR

C Lynne Burek, Department of Pathology, The Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Autoantibodies are antibodies that have the capacity to bind to self antigens. Autoantibodies are evaluated for a number of reasons and may be used as an aid in diagnosis of disease, either by inclusion or exclusion. In some cases the autoantibodies may actually cause disease. However, they are more frequently used as markers in a variety of ways. They may help distinguish between different forms of a condition, which may result in using different therapeutic strategies. Changes in antibody quantity may be used to monitor successful therapy or disease exacerbation. They may be used as indicators of individuals at risk for future diseases in disorders that are familial. Autoantibody tests are never used by themselves for diagnosis of disease. The total picture of the patient must always be considered as autoantibodies can also be found in normal individuals. Autoantibodies in normal individuals range in frequency according to age and sex; generally, the lowest frequency is in young males, the highest in elderly females.

Methods for identifying autoantibodies

Techniques for demonstrating autoantibodies are frequently ordained by the location and properties of the antigen and the required level of sensitivity. Early assays, some of which are still used today, included agglutination and precipitation techniques. Agglutination employs stable suspensions of beads (e.g. latex) or erythrocytes coated with the appropriate soluble antigen. Autoantibodies cross-link the coated particles forming the complex lattice structure of agglutination. Thyroid autoantibodies are frequently detected by indirect hemagglutination (i.e. by using erythrocytes coated with thyroid antigens), while latex agglutination remains the most widely used test for the measurement of rheumatoid factor (i.e. by using latex beads coated with gammaglobulin). Although precipitation in fluid or gelified media (e.g. immunodiffusion) is less sensitive than agglutination, it is still appropriate for the demonstration of antibodies to complex mixtures of soluble antigens, such as certain nuclear antigens that have not yet been purified.

Indirect immunofluorescence (IIF) is the most commonly used test for the detection of tissue-specific autoantibodies because of its wide range of applications. Briefly, serum is placed on a tissue section

(frozen section, 4 μ m thick). If autoantibodies are present, they will bind to the appropriate antigen. Excess serum is washed away. A second reagent, antihuman immunoglobulin conjugated to a fluorescent dye (usually fluorescein isothiocyanate, FITC), is then incubated with the tissue section. Unbound reagent is again washed away. Autoantibodies are detected using a microscope (transmission or incident light illumination) with an appropriate light source (usually mercury vapor or halogen quartz) and filter system that will enable the fluorescent markers to be seen. IIF can detect multiple antibodies on a single tissue or on a multiple tissue block, and thus has considerable value as a screening test. It is particularly valuable in testing for autoantibodies for which the antigen has not yet been characterized or for unexpected antibodies. These latter antibodies may be missed by an assay employing only purified antigens. With IIF, the reaction site can be seen, and thus the location of the cellular antigen can be determined. In a few cases, however, the major autoantigen associated with a particular autoimmune disorder has been isolated. Subsequently, more sensitive quantitative tests, such as hemagglutination, enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay (RIA), have been developed using the isolated antigen fraction and have replaced IIF. Autoantibody isotype can be evaluated by using heavy chain-specific anti-immunoglobulin, although this is also true for any of the indirect detection tests.

Indirect immunoperoxidase (IIP), although similar to IIF in performance, utilizes an enzyme (e.g. horseradish peroxidase) to hydrolyze a substrate to form a colored precipitate at the site of antibody binding, rather than a fluorescent marker. Another enzyme, alkaline phosphatase, can also be used in a similar fashion. Although IIP has certain advantages over IIF, as the reaction can be seen under a standard light microscope and the slide can be stored indefinitely, it is not totally without problems. Endogenous peroxidases may cause false-positive results. The same time and effort must go into establishing this technique as for IIF. IIP is reported to be more sensitive than IIF, but each individual assay model must be evaluated independently.

RIA is a highly sensitive technique for the detection of autoantibodies; however, it requires defined antigens and the use of radioisotopes, and the trend

is to replace radiolabeled compounds with enzyme-labeled substances and many of the former RIAs have therefore been converted to ELISAs.

The western immunoblot has recently been introduced for clinical diagnosis. It does not require a pure antigen but is relatively slow and expensive. Briefly, the antigen solution is separated by electrophoresis in polyacrylamide gel on the basis of relative molecular weight. The proteins in the gel are electrotransferred to a nitrocellulose membrane and cut into strips. Individual strips are reacted with patient serum, washed and incubated with an anti-immunoglobulin conjugated to an enzyme. Finally, the strips are treated with an enzyme substrate and the site of antibody localization is identified by a color precipitate. Western blot will indicate the approximate molecular weight of the antigen that is recognized by the autoantibody, but will not identify the protein itself.

Autoantibodies

There is a spectrum of autoantibody reactivities ranging from organ-specific to non-organ-specific autoantibodies. Organ-specific autoantibodies react to antigens of only one tissue, such as to thyroid tissue. Non-organ-specific autoantibodies react with antigens common to all tissues, such as to different nuclear antigens, and are often associated with more generalized disorders, such as systemic lupus erythematosus. There is also a small group of intermediate autoantibodies with specificity to particular tissues but with a widespread distribution, such as smooth muscle. The description of the autoantibodies and their tests, presented below, will feature this range of reactivities, summarized in Table 1.

Thyroid-specific antigens

Thyroglobulin

Thyroglobulin autoantibodies can be demonstrated by several procedures, such as precipitation in agar, IIF, indirect hemagglutination of cells coated with thyroglobulin, RIA and ELISA. At present, hemagglutination is the most commonly employed technique for the detection of antibodies against thyroglobulin. The ELISA is increasingly used for the measurement of antibodies to thyroglobulin and will additionally detect antibodies that are nonagglutinating. Thyroglobulin antibodies are found in individuals with chronic thyroiditis, myxedema, Graves disease, goiter, thyroid tumors and other polyendocrine disorders. The highest titers are found in patients with autoimmune thyroid disorders. Low titers of thyroglobulin antibodies may be found in normal

individuals. The prevalence of such antibodies in subjects without overt thyroid disease is higher in women. The incidence also increases with age, so that 18% of women over 40 years old may have antibodies to thyroglobulin. Total thyroglobulin antibody is not a specific marker of autoimmune thyroiditis as so many other conditions also show the presence of this antibody. Recent evidence suggests, however, that there may be disease-related epitope specificity of the autoantibody. The disease-related antibodies were detected by competitive inhibition ELISA experiments using murine monoclonal antibodies.

Microsomal antigens (TPO) of thyroid epithelial cells

The microsomal antigen has been identified chiefly as the thyroid peroxidase enzyme (TPO) of the thyroid epithelial cell. However, purified TPO is not readily available for use in diagnostic tests. The most commonly used tests for the microsomal autoantibodies are either IIF, using primate thyroid tissue, or hemagglutination. ELISA, RIA or a chemiluminescence-based assay may also be employed. The antibodies to the microsomal antigens belong predominantly to the immunoglobulin G (IgG) class and, when detected by IIF, stain the cytoplasm of thyroid cells. The IIF test for antibodies to thyroid microsomal antigens is positive in approximately 70–90% of patients with chronic thyroiditis. It is also positive in 64% of patients with primary hypothyroidism, 50% of patients with thyrotoxicosis, 10% of patients with simple goiters, and 17% of patients with thyroid tumor. It can also be found in normals at a low frequency and titer.

Thyrotropin receptor

Autoantibodies binding to the thyrotropin (TSH) receptor on the surface of thyroid epithelial cells are believed to be the direct cause of the hyperthyroid state in Graves' disease. The thyroid-stimulating autoantibodies (TSAbs) bind near to or with the TSH receptor and mimic TSH activity, resulting in uncontrolled stimulation as there is no negative feedback control. Tests for TSBAs are primarily of two types: bioassays or binding assays. Most bioassays have limited utility because they are cumbersome and require scarce materials, such as viable slices of fresh human thyroid tissue. Bioassays, however, evaluate functional aspects of the antibodies as their endpoint. Binding assays are based on competition between ¹²⁵I-labeled TSH and patient autoantibodies for binding to thyroid preparations. Some confusion has been created by the heterogeneity of the autoantibodies and the diversity of the assays for their

Table 1 Detection of autoantibodies

<i>Autoantibody to:</i>	<i>Primary method of detection^a</i>	<i>Primary associated disorders</i>
Thyroid		
Thyroglobulin	Hemagglutination ELISA	Autoimmune thyroiditis, primary myxedema
Microsomal (thyroid peroxidase)	IIF (mk-thyroid) Hemagglutination	Autoimmune thyroiditis, primary myxedema
TSH receptor	Bioassay Binding assay	Graves' disease
Parietal cell	IIF (ro-stomach)	Atrophic gastritis, pernicious anemia
Adrenal	IIF (mk-adrenal)	Idiopathic Addison's disease
Ovary	IIF (mk-ovary)	Infertility
Testes, sperm	IIF (mk-testes) Agglutination Immobilization	Infertility
Pancreas islet cell	IIF (hu group O or mk-pancreas)	Insulin-dependent diabetes mellitus
Parathyroid	IIF (mk-parathyroid)	Idiopathic hypoparathyroidism
Pituitary	IIF (hu- or mk-pituitary)	Growth disorders
Skin		
Basement membrane zone	IIF (hu-skin, mk-esophagus)	Bullous pemphigoid
Intercellular substance	IIF (hu-skin, mk-esophagus)	Pemphigus vulgaris
Muscle		
Smooth	IIF (ro-stomach)	Chronic active hepatitis
Cardiac striated	IIF (ro-heart)	Autoimmune cardiomyopathy
Skeletal striated	IIF (ro-skeletal)	Myasthenia gravis
Endomysial	IIF (mk-esophagus)	Celiac disease
Acetylcholine receptor	RIA, ELISA	Myasthenia gravis
Neutrophil cytoplasm (C-ANCA, proteinase 3, P-ANCA, myeloperoxidase)	IIF (hu-PMNs), ELISA	Wegener's granulomatosis, microscopic vasculitides
Nuclear antigens (ANAs)	IIF (ro-liver, Hep-2 cells), ELISA Hemagglutination Immunodiffusion	Systemic lupus erythematosus, connective tissue disorders
Mitochondria	IIF (ro-kidney)	Primary biliary cirrhosis
Phospholipids	ELISA	Antiphospholipid syndrome
Rheumatoid factor	Latex agglutination Nephelometry	Rheumatoid arthritis

PMN, polymorphonuclear leukocyte.

^aSpecies and tissue substrate used: mk, monkey; ro, rodent; hu, human.

demonstration. Different specificities of autoantibodies to the thyroid epithelial cell surface on or near the TSH receptor may be represented.

The detection of these antibodies in Graves' patients ranges from 55 to 95%, depending on the assay. The TSAb assay is of greatest utility in conditions where conventional test results are equivocal or where clinical signs and symptoms are not readily apparent (e.g. ophthalmopathy in the absence of other features). Moreover, the TSAb assay is usually negative in patients with thyrotoxicosis in association with thyroid nodules, with cancer, or in patients with subacute thyroiditis. Therefore, a positive test confirms a diagnosis of Graves' disease with a high degree of confidence. The assay can be used

to monitor patient therapy, as successful treatment of Graves' disease with propylthiouracil may result in lowering levels of TSAb antibodies. The assay has also proven useful in the diagnosis of neonatal thyrotoxicosis.

Gastric parietal cells

Autoantibodies to antigens of gastric parietal cells (parietal cell antibodies) occur with high frequency in patients with pernicious anemia and atrophic gastritis. Autoantibodies to gastric parietal cells are frequently found simultaneously with thyroid antibodies, although these cells are not usually considered as part of the endocrine system. These

autoantibodies are readily detected by IIF with sections of rodent stomach (mucosa) as tissue substrate. The pattern of staining resembles that seen with mitochondrial antibodies; therefore, a control test on kidney should also be performed. Parietal cell antibodies are found in 90% or more of patients with pernicious anemia. Recently, the autoantigen has been identified as the α and β subunits of gastric H^+,K^+ -ATPase. An ELISA using this enzyme and a western blotting technique using gastric extracts have been developed. These antibodies are also present in a number of other conditions, such as chronic thyroiditis (33%), Sjögren's sicca syndrome (15%), atrophic gastritis (60%), gastric ulcer (22%), etc. The antibodies are also found in the normal population, with an incidence that varies according to age and sex; i.e. from 2% in subjects under 20 years old to 16% in subjects over 60 years old. They are more frequent in women than in men.

Other endocrine organs

Autoimmunity also develops against other endocrine organs such as the adrenal gland, pancreas islet cells, parathyroid, pituitary and ovary. The autoantibodies are much less prevalent than with thyroid disease but, if present, help in diagnosis. The reactivities, assays and primary associated disorders are summarized in Table 1.

These autoantibodies share certain characteristics. Antibodies bind to antigens associated with the cytoplasm of cells, usually to unidentified antigens. The antibodies belong predominantly to the IgG class and, in general, have rather low titers (not higher than 100) and are rarely found in normal individuals.

The presence of antibodies to particular endocrine organs suggests that the disease is idiopathic and not of malignant, infectious or other nature. However, it is not uncommon for patients with autoantibodies to one endocrine organ to have multiple endocrine reactivities. Furthermore, not all patients with a particular disorder have the autoantibodies, so that a negative test obviously does not exclude a particular diagnosis. On the other hand, a positive test is not necessarily diagnostic, in that the patient might have other autoantibodies to endocrine organs without clinical disease. An interesting feature of autoantibodies to islet cells of the pancreas is that the percentage of positive sera decreases with time after onset of disease.

Skin antigens

Patients with autoimmune skin disease, such as pemphigus vulgaris or bullous pemphigoid (BP) develop autoantibodies that bind to epidermal antigens. These antibodies are identified by IIF, using tissue sections of skin (e.g. foreskin) or other squamous epithelium (e.g. monkey esophagus) as tissue substrate. Patients with pemphigus vulgaris show serum autoantibodies to the intracellular area of the epidermis in 80–90% of cases. These antibodies are IgG, most of them bind complement, and they are pathogenic, as demonstrated by serum transfer experiments. Low levels of pemphigus-like autoantibodies are sometimes found in other conditions, such as burns and systemic lupus erythematosus, as well as in normal individuals. These antibodies appear to correlate with disease activity and may be used to monitor therapy.

Over 70% of BP patients exhibit autoantibodies that bind to the basement membrane zone between the dermis and the epidermis, appearing as a linear band of staining. False positives are rare. Evidence from *in vitro* and *in vivo* studies shows that these autoantibodies are pathogenic.

Muscle antigens

Smooth muscle

Sera from patients with chronic active hepatitis contain antibodies to smooth muscle antigens that are detectable by IIF and bind smooth muscle of all organs. The major antigen of the smooth muscle is actin. The antibodies belong mainly to the IgG class, but they can also be found in the IgM class. The test is performed on unfixed cryostat sections of rodent stomach as substrate. Smooth muscle antibodies are found in 40–70% of patients with active chronic hepatitis, with lower titers found in 50% of patients with primary biliary cirrhosis, and 28% of patients with cryptogenic cirrhosis. These antibodies are also found at low titer in patients with acute viral hepatitis, infectious mononucleosis, asthma, yellow fever and malignant tumors (carcinomas of the ovary, malignant melanoma). They have been found in less than 2% of the normal population.

Cardiac muscle

The presence of antibodies to cardiac striated muscle in patients with cardiomyopathy may help to distinguish autoimmune myocarditis from other forms of myocarditis (e.g. viral). This finding, in turn, may influence therapy. These antibodies are most readily detected by IIF with sections of rat heart as tissue substrate and bind to fibrillary antigens as well as

to sarcolemma or subsarcolemma antigens. The most severe cases of myocarditis or dilated cardiomyopathy have been associated with high titers of IgG antibodies specific for cardiac and not skeletal striated muscle. Many normal individuals may have low titers of antistriated muscle antibodies, but they are generally of the IgM class and react with both skeletal and cardiac striated muscle.

Endomysial

Autoantibodies to endomysial membranes, the outside lining of smooth muscle bundles, are found in patients with dermatitis herpetiformis and with celiac disease, and are primarily IgA. The major test is IIF using the lower part of monkey esophagus as tissue substrate. It appears to be a more specific and sensitive marker of celiac disease than testing for reticulin autoantibodies. In a few patients with celiac disease that have an IgA immunodeficiency, the antibody to endomysial antigens were found to be IgG. Isotype-specific anti-immunoglobulins conjugated to FITC are used as specific reagents to determine the relevant autoantibodies.

Acetylcholine receptor

Autoantibodies to acetylcholine receptor (AChR) are present in 80–95% of sera from patients with myasthenia gravis. Variations in the reported incidence of these antibodies are due to the different methods (complement fixation, passive hemagglutination, and various RIAs and ELISAs) used for their detection. In addition, there are heterogeneous specificities of antibodies to AChR; i.e. some that react to determinants other than the neurotoxin-binding site, others that react with the neurotoxin-binding site or the extrajunctional receptors, and others that are species specific. Since the cross-reactivity of human antibodies to AChR with receptors from other species is limited, human skeletal muscle is preferred as the source of AChR.

The procedures usually employed to detect circulating antibodies to AChR are RIAs. A direct binding assay is based on the inhibition of toxin binding to the receptor by the antibodies. A double antibody assay is based on the use of a labeled neurotoxin–receptor complex and thus quantitates receptor antibodies by measuring their binding to sites other than the acetylcholine- or neurotoxin-binding site.

Neutrophil cytoplasmic antigens

Antineutrophil cytoplasmic autoantibodies (ANCA) have recently become an important diagnostic tool for vasculitis associated with Wegener's granuloma-

tosis and certain other microscopic vasculitis and glomerulonephritis disorders. The antibodies are detected primarily by IIF on isolated human neutrophils as substrate. Differences in fixation of the cells can separate the antibodies into two distinct groups with different specificities: C-ANCA and P-ANCA. Ethanol fixation causes a redistribution of the antigens of the P-ANCA specificity causing a 'perinuclear' (P) picture of the fluorescent staining, while C-ANCA remains cytoplasmic (C). Formaldehyde fixation prevents the redistribution of the P-ANCA antigens so that the binding of both antibodies appears cytoplasmic. The major antigen of the C-ANCA specificity has been reported as proteinase 3 of the α granules, while the major antigen of P-ANCA has been identified as myeloperoxidase. ELISA tests using specific antigens are currently being developed. The appearance and change in titer of these antibodies appear to be good indicators of remission/exacerbation and severity of disease.

Mitochondrial antigens

Autoantibodies to mitochondrial antigens, detectable by IIF on rat kidney sections, are primarily associated with patients with primary biliary cirrhosis. The major antigen is reported to be a component of the pyruvate dehydrogenase enzyme complex. The antibodies belong to the IgG, IgA and IgM classes. The mitochondrial antibodies stain the cytoplasm of cells from different organs, such as thyroid or kidney, that varies with the mitochondrial content of the cells. Distal tubules of kidney and gastric parietal cells show a bright, uniform, cytoplasmic fluorescence, whereas renal proximal tubules show a characteristic coarse, granular, duller staining.

Mitochondrial antibodies are detected in 87–98% of patients with primary biliary cirrhosis. They are also observed in 25–28% of patients with active chronic hepatitis and in 25–30% of patients with cryptogenic cirrhosis. They are only seldom observed in patients with extrahepatic biliary tract obstruction and occur very rarely in normal subjects.

Nuclear antigens

A wide range of antinuclear antibodies (ANAs) occur against antigens associated with cell nuclei, including autoantibodies to DNA, histones, small nuclear RNP (snRNP), Ro/SS-A, La/SS-B, and tRNA synthetase. Many fine specificities have been defined amongst the various types of ANA. Diseases in which ANAs are particularly prevalent include mixed connective tissue disease, systemic lupus erythematosus, the CREST syndrome and progressive systemic sclerosis.

They are also commonly seen, although at a lower frequency, in rheumatoid arthritis and Sjögrens syndrome. IIF is used as an initial screening test for the occurrence of ANAs. Antibodies to many of the specific antigens can be measured in ELISA, although RIA (including the Farr assay and PEG assay), immunoblot, immunoelectrophoresis, RNA precipitation, and the LE-cell test are all commonly employed.

Phospholipid antigens

Antiphospholipid autoantibodies are a heterogeneous group of antibodies with specificity to a phospholipid-protein complex. The protein associated with cardiolipin has been identified as a β_2 -glycoprotein (β_2 -GPI). Some investigators suggest that this is the relevant autoantigen in patients with antiphospholipid syndrome, although the relative importance of these two molecules has not yet been fully clarified. The most sensitive test used is an ELISA using cardiolipin or other phospholipids to coat ELISA plates. Standardization of the various tests for the different phospholipids has been a problem. However, even so, the clinical utility has been established for antiphospholipid syndrome.

Rheumatoid factor

Rheumatoid factor represents a group of antibodies characterized by their ability to react with antigenic determinants on the Fc portion of immunoglobulin. Serum from patients with rheumatoid arthritis agglutinate sheep red blood cells (SRBCs) sensitized by rabbit anti-SRBC and this is the basis of the Waaler-Rose test. However, latex beads coated with Cohn fraction II as the source of IgG antigen, devised by Singer and Plotz, is the most widely used test today.

Other techniques for demonstrating rheumatoid factor include nephelometry and ELISA. Laser nephelometry and rate nephelometry utilize the changes in light-scattering properties of aggregated IgG when exposed to sera containing rheumatoid factor. These tests are reported to be equally sensitive and specific and more reproducible than established agglutination techniques, and they lend themselves well to automation.

AUTOANTIGENS

Ian R Mackay, Department of Biochemistry and Molecular Biology, Monash University, Melbourne, Australia

Antigens, and autoantigens, are detected by their capacity to participate in immunological reactions. When antigens provoke an immune response they behave as immunogens. Immunogenicity depends on various properties of the antigen, including its mode of presentation, local concentration and the immune capacity of the responding individual. For autoantigens there is an additional constraint on the response, this being the degree of natural tolerance to the autoantigenic particle.

Just as there is reciprocity between antigen and antibody, so too is there reciprocity between autoantigen and autoantibody. In addition, autoantigen is a self constituent, and thus the autoantibody reactive with it *in vitro* is assumed to be reactive *in vivo* as well. The individual's immune system scrutinizes a 'universe' of potential antigens: those that are foreign, extrinsic or nonself, and those that are constitutive, intrinsic or self, i.e. autoantigens. However, differences between 'foreign' and 'constitutive' antigens may be slight. Thus, some bodily constituents are absolutely specific or unique to an individual but others may be shared, at least within the species, or across species, or may be so conserved as to be represented throughout most living organisms.

When speaking of autoantigens, the context is usually that of reactivity with autoantibody, i.e. a product of the B cell lineage; however, most autoantigens would also need to be reactive with a T lymphocyte for induction of an immune response and for expression of pathogenic effects. T cell reactivity with antigen and especially with autoantigen, compared with B cell reactivity, is harder to detect and quantify; however, current assays based on proliferative responses or release of cytokines are becoming increasingly reliable.

The interaction *in vivo* between autoantibody and antigen is a potential cause of disease – autoimmune disease. Whether all self constituents behave as autoantigens is uncertain; for some, autoantibody is never demonstrable, so that tolerance to them is absolute. For many self constituents there may be autoantibodies demonstrable but seldom or ever is there any associated disease; indeed there is an increasing awareness of the wide range of 'natural' autoantibodies in health to various autologous constituents. In other instances autoantibody is only transiently present, e.g. after injury. The development of disease

after an autoimmune response may thus depend on additional factors, of which many are under genetic control. These include abundance and accessibility of the autoantigen, the capacity for presentation by antigen-presenting cells, the appropriate stimulation of cognate T cells, the efficiency of regulation of the immune response, the affinity and subclass of the autoantibody produced by B cells, and others.

Autoantigens have accrued a rather loose terminology among clinical immunologists who, hitherto, have referred to large cellular organelles as 'antigens', for example nuclear, mitochondrial, microsomal, etc. This parlance was convenient for clinical diagnostic purposes, since antinuclear, antimitochondrial and other tissue antibodies had disease associations, but it reflected ignorance of the constituents of cellular organelles to which autoimmune responses are directed. This is changing with molecular immunology leading to the cloning of cDNAs which code for autoantigenic polypeptides. An antigen, of whatever provenance, is actually a mosaic of determinant groups or epitopes, described by N. K. Jerne as follows: 'An antigen particle carries several *epitopes* (= surface configurations, single determinants, structural themes, immunogenic elements, haptenic groups, antigenic patterns, specific areas). An antibody molecule normally carries, apart from its epitopes, two paratopes (= combining sites, reactive segments, complementary cavities, specific receptors). Epitopes are potentially immunogenic when present on an appropriate carrier: they may induce the formation of paratopes.'

The several or more epitopes of autoantigens are called autoepitopes. These may be reactive with paratopes of the autoantibody, and with the corresponding cell surface immunoglobulin molecule which serves as the antigen receptor for B cells: these are B cell epitopes. Also there are epitopes which engage T cells, T cell autoepitopes; the (moderately) predictive algorithms proposed for identifying T cell epitopes of foreign antigens are applicable also to autoantigens.

Epitopes, including autoepitopes, for B cells may be represented by linear sequences of peptides but more often are created by the conformational structure of the protein, and may require a substantial sequence of the antigenic molecule for their formation. Examples among the autoantigens include the

Ro(SS-A) and La(SS-B) ribonucleoproteins, the E2 subunit of pyruvate dehydrogenase complex (PDC-2) and glutamic acid decarboxylase.

Epitopes for T cells are represented by short linear sequences, nine or more amino acids, that are products of the processing of antigenic molecules, yielding peptides that bind into the polymorphic antigen-binding cleft created by the molecular configuration of major histocompatibility complex (MHC) molecules; particular residues, 'anchor' residues, are critical for this binding. A conformation of amino acids, known as a disease susceptibility motif, in the antigen-binding cleft of the MHC molecule, that can effectively bind a T cell epitope of an autoantigen may explain some of the well-known HLA associations with disease. Molecular sequences that bind to MHC molecules (in reality T cell epitopes) were formerly called agretopes but, with newer knowledge, this term has lapsed. Epitopes of antigens including autoantigens that react with and stimulate T cells can be recognized by assays that depend on cellular proliferation or release of lymphokines; however, progress has been slow.

The question often arises as to whether autoantigens actually function as immunogens. The focused nature of autoimmune responses strongly suggests that these are 'antigen driven' and, if this were so, the drive would be directed to the helper CD4 T cell. It remains uncertain whether the antigen drive, for B or T cells, is derived from autoantigen or a cross-reactive extrinsic structure with a closely similar molecular shape, as postulated by the mimicry hypothesis; alternatively, anti-idiotypic antibody against, say, antibody developed to an infectious agent could act as an 'internal image' of an autoantigen and so provide an immunogenic stimulus.

Autoantigens are so numerous and diverse that classification is hardly feasible, but this could be based on their site of origin (Table 1) as follows: cell membranes; cell cytoplasm; cell nuclei; specialised tissue constituents; secreted molecules; neural products.

From the standpoint of pathology, the autoantigens listed in Table 1 have varying degrees of relevance. The reactivity of various 'natural' autoantibodies present in normal sera is irrelevant to actual pathogenesis. Then there are autoantibodies that can be termed 'marker' antibodies, as they point to a disorder of immune tolerance as a cause of the disease with which they are associated, but do not *per se* appear to be pathogenic; and there are other autoantibodies which are truly pathogenic, such as those reactive with cell membrane structures including receptors for neurotransmitters and hormones.

Autoantigens associated with intracellular organelles, nuclear or cytoplasmic, raise interesting issues

in that many of these have a close if not specific relationship with a particular disease, and are therefore useful diagnostically. Examples include autoantibodies to centromere or Scl-70 antigens which occur in scleroderma, to ribonucleoprotein antigens in lupus-related diseases, and to mitochondrial antigens in primary biliary cirrhosis (PBC). However, for pathogenicity to be ascribed to such antigens, one or even both of two requirements should be fulfilled. One would be that the autoantigen becomes translocated to the cell surface, and here the PDC-E2 autoantigen of primary biliary cirrhosis is an interesting example as it is demonstrable at the surface of biliary ductular cells of patients with PBC; this observation foreshadows interests for autoimmunity in mechanisms that may influence intracellular transport of molecules between nucleus, cytoplasmic organelles and cell membranes. The other requirement would be a capacity for autoantibody to penetrate the membrane of intact cells to access intracellular organelles; there are data supporting this but the matter is controversial.

The category 'neural products' (Table 1) contains reactants for interesting autoantibodies in paraneoplastic autoimmune neurodegenerations, central or peripheral, that are rare accompaniments of ovarian, lung and breast cancers. The cancer itself presumably generates the neural antigen and facilitates its immunogenic presentation.

A better understanding of the structure of autoantigens has come from advances in analytical biochemistry, including gel chromatography and transfer western immunoblotting, and also molecular biology, including antibody probing of gene expression libraries and phage display libraries. These techniques have identified the reactive polypeptide antigens in various of the cellular organelles and have yielded cloned cDNAs which allow for gene sequencing and mapping of autoepitopes; screening of phage display libraries may occasionally reveal linear mimotopes of conformational autoantigens. There have been interesting outcomes, as follows:

1. There is an increasing availability of recombinant proteins for diagnostic assays, ELISAs and radioimmunoprecipitation which, by reason of greater sensitivity and versatility, are supplementing detection of autoantibodies by immunofluorescence.

2. Epitope mapping is revealing that, for most autoantigens, there are multiple and apparently structurally different epitopes recognized by antibody. This impinges on the concept of 'molecular mimicry', which holds that resemblances between a sequence in a host protein and a microorganism can result in production of autoantibody. The presence

Table 1 Examples of autoantigens and disease associations

<i>Autoantigen</i>	<i>Related diseases</i>
<i>Cell membranes</i>	
Blood cells	Hemolytic diseases: hemolytic anemia, thrombocytopenic purpura, neutropenia
Receptor structures for acetylcholine thyrotropin (TSH) insulin	Myasthenia gravis Graves disease (thyrotoxicosis), goiter (?) Diabetes, insulin-resistant type
Nerve cells: myelin of oligodendroglia, Schwann cells	Experimental autoimmune encephalomyelitis, neuritis
Liver cells: asialoglycoprotein receptor	Autoimmune hepatitis, type 1 (?)
<i>Cytoplasm, organelles</i>	
Tissue specific	
gastric H ⁺ , K ⁺ -ATPase, α and β subunits	Autoimmune gastritis, pernicious anemia
thyroid peroxidase (microsomal antigen)	Hashimotos thyroiditis
adrenal 21-hydroxylase	Addisons disease
pancreatic islet glutamic acid decarboxylase; ICA512/IA-2/37-40k; insulin	Type I diabetes mellitus
salivary duct cell	Sjögrens syndrome with rheumatoid arthritis
neutrophil cytoplasmic proteinase 3 and myeloperoxidase (ANCA)	Wegener's disease, vasculitic diseases and others
Non-tissue specific	Autoimmune hepatitis, type 2
cytochrome P450 2D6 (liver-kidney microsomes)	Primary biliary cirrhosis
2 oxo-acid dehydrogenase enzymes (mitochondria, M2)	
phosphoproteins P0, P1, P2 (ribosomes)	Systemic lupus erythematosus (SLE)
cytoskeletal actin (smooth muscle antibody)	Autoimmune hepatitis, type 1
stress (heat-shock) proteins	Rheumatic diseases (?)
transfer RNA synthetases (Jo1)	Polymyositis and variants
<i>Nuclei</i>	
DNA	SLE
Histones	SLE, particularly drug related; various rheumatic diseases
U (uridine-rich) RNA-protein complexes	
U1-RNP	Mixed connective tissue disease
U1, U2, U4-6 RNPs (Sm antigen, various epitopes have been mapped)	SLE
Ro-La	
Ro(SS-A)	Primary Sjögrens syndrome; cutaneous LE; fetal heartblock
La (SS-B)	Primary Sjögrens syndrome; SLE
Centromere	Scleroderma, CREST variant
Topoisomerase I (Scl-70)	Scleroderma, systemic sclerosis
Nucleolus	Systemic sclerosis; undifferentiated rheumatic diseases
fibrillarin	
nucleolar RNP	
Proliferating cell nuclear antigen (cyclin)	SLE (rarely)
<i>Specialised tissue products</i>	
Squamous epithelium	
desmosomes (desmoglein 1,3)	Pemphigus vulgaris, pemphigus foliaceus
hemidesmosomes (BPAG 1 & 2)	Bullous pemphigoid
Striated muscle, sarcomere, cytoskeletal proteins	Myasthenia gravis, with thymoma
Cardiac muscle, sarcolemma	Myocarditis, rheumatic carditis
Chondrocytes, collagen type II	Rheumatoid arthritis
Glomerular basement membrane, collagen type IV	Glomerulonephritis (Goodpasture type)
Retina, S antigen	Uveitis
Sperm antigens	Male infertility; orchitis (?)
Colon mucosal cell	Ulcerative colitis (?)
β_2 glycoprotein 1 (cardiolipin)	Antiphospholipid syndrome, thromboembolism
<i>Secreted products</i>	
Gastric intrinsic factor	Atrophic gastritis, pernicious anemia
Immunoglobulin G, Fc region	Rheumatoid arthritis
Thyroid colloid	Atrophic hypothyroidism; Hashimotos thyroiditis
Insulin	Type I diabetes mellitus

of several epitopes on autoantigens, and/or the existence of conformational epitopes, could limit the appeal of the molecular mimicry hypothesis because it is unlikely that the several epitopes of the autoantigen would be conformationally similar, or that the extrinsic antigen would have multiple mimicry epitopes; however, mimicry could exist for a single shared or cross-reactive epitope recognized by the CD4 helper T cell that could then recruit successive B cell epitopes into the autoimmune response, a process known as epitope spreading.

3. The epitope recognized by autoantibody is frequently associated with an active site of an enzyme or other functional molecule, and the antibody can be shown to inhibit the function *in vitro* of the cognate autoantigenic enzyme. For example, the major epitope of PDC-E2, the M2 autoantigen of PBC, is the functional lipoyl domain, and the reaction of PBC serum with this domain specifically abrogates the catalytic function of the PDC enzyme *in vitro*.

4. There is a possibility that autoantigens may have 'disease-specific' epitopes that differ in site or structure from epitopes that are reactive with non-disease-specific natural autoantibodies.

5. Various intracellular antigenic molecules have been functionally characterized at the molecular genetic level by the use of autoantibodies as research reagents. Examples, of which there are many, include the U-ribonucleoproteins which splice out introns from mRNA, the La ribonucleoprotein which participates in the termination of transcription of RNA polymerase III, and the Ku antigen which participates in recombination and repair of DNA.

One major need at present is to verify T cell responses to autoantigens and map the relevant epitopes, noting that autoepitope-responsive T cells have a low representation among peripheral blood cells and, even in affected tissues, will be 'diluted' by nonspecifically reactive cells in inflammatory exudates. Another need is to understand why particular molecules or related groups of molecules are singled out among numerous others as autoantigenic reac-

tants, i.e. why there is failure of tolerance to these particular tissue constituents. This will require better understanding of how 'nascent' self reactive T or B lymphocytes are deleted in the thymus or bone marrow respectively during ontogeny, and how self reactive lymphocytes that escape this process are tolerized in the periphery in postnatal life.

AUTOIMMUNE DISEASE, INDUCED ANIMAL MODELS

W J Penhale, Institute of Molecular Genetics and Animal Disease, School of Veterinary Studies, Murdoch University, Murdoch, Australia

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The first indication that the immune system could be experimentally provoked into dangerous self reactivity stems from the early 1930s when Rivers and his colleagues induced encephalomyelitis in monkeys by the injection of brain material. Some 20 years later, Voisin and coworkers made the, quite literally, seminal observation that testicular lesions could be similarly induced by testicular extracts including spermatozoa. Although these studies provided the prototype animal models of autoimmune diseases, the foundations of experimental autoimmunity were not truly laid until Rose and Witebsky demonstrated in a series of classical studies that both antibodies to thyroid constituents and thyroiditis could be induced by immunizing rabbits with thyroid extracts in Freund's complete adjuvant. Since then, many experimental models have been developed in a broad range of animal species and, consequently, the 1975 prediction of Wick – that autoimmune disease may be induced in any organ provided the investigator tries hard enough – seems ever more likely. In addition, new experimental approaches not involving specific immunization have been introduced and these have widened the scope and range of disease models now available for study. These later models have opened alternative avenues for investigation and, in consequence, new conceptual insights into the autoimmune process have been made.

As a group, induced models may be defined as those in which an autoimmune process is superimposed on otherwise normal, unaffected animals by a variety of treatments or manipulations. They contrast with the spontaneous models where disease occurs without intervention and is largely, although not entirely, determined by genetic composition. In consequence, whilst spontaneous models are limited to a particular genome, induced models are well suited to the investigation of genetic influences by their imposition on inbred strains of differing genetic constitution. They also have the particular advantages that normal syngeneic animals are available for parallel control studies, as recipients in adoptive transfer experiments, and also for the provision of cells for reconstitution studies in depleted animals.

The extensive range of induced animal models that is currently available has resulted from an expanding variety of induction strategies and can be con-

veniently grouped on this basis. Since the methods employed often reflect fundamental differences in both the triggering and pathogenic mechanisms, each type provides its own insight into autoimmune pathogenesis and has particular advantages for research in selected areas. Despite these widely differing inductive procedures, however, it is likely that the terminal pathogenic pathways coincide when a common organ is involved. These aspects will be discussed in the following sections which briefly review the various models currently available.

Methods of experimentally inducing autoimmunity

1. Induction of autoimmunity by immunization ('immunization models')

This approach, the first to be introduced, has been of primary importance in establishing the validity of the autoimmune concept. Furthermore, since it has been possible by this means to raise autoimmune responses to an extensive range of self components (Table 1), it is evident that potentially autoreactive cells are not only a normal component of the immune repertoire of every individual but also that they are quite capable of being activated under appropriate conditions. As a corollary, it also follows that, under normal circumstances, these cells are effectively subjugated by one or more regulatory mechanisms. In consequence, it is generally necessary to inject native autoantigens in combination with powerful nonspecific immunostimulants such as Freund's water-in-oil adjuvant in order to override these inhibitory influences. As an alternative procedure, the immunogen can be altered self components or material derived from other species which may provide a more effective autoimmune stimulation by way of 'modified self' or cross-reactive antigenicity. Weigle, for example, used rabbit thyroglobulin to induce thyroiditis in mice and the injection of rat erythrocytes into mice also induces antibodies to mouse erythrocytes and transient anemia. Presumably, under these circumstances, the inclusion of new antigenic determinants can provide a bypass mechanism permitting new T cell help for the generation of autoimmune responses.

Immunization models have been extensively used

Table 1 Induction of experimental autoimmunity by immunization with autoantigens

<i>Target organ/tissue</i>	<i>Animal species</i>	<i>Analogous human disease</i>
Thyroid follicles	Rabbit, mouse, guinea pig, rat, monkey, chicken, dog	Hashimoto's thyroiditis
Adrenal cortex/medulla	Guinea pig, rabbit, rat (Lewis, BN), mouse (CF1, BSVS), monkey, dog	Autoimmune adrenal failure (Addison's disease)
Pituitary/adenohypophysis	Rat, rabbit	Lymphocytic adenohypophysitis
Parathyroid	Rat, dog, chicken, mouse	Autoimmune parathyroiditis
Pancreas (islet cell)	Rat, mouse, rabbit	Type I diabetes
Central nervous system neurons	Rat (Lewis), guinea pig (strain B), mouse, sheep, monkey	Multiple sclerosis
Eye (uvea/retina)	Guinea pig (Hartley and NIH)	Autoimmune uveitis
Kidney (tubules/glomeruli)	Rat (BN) Rat	Autoimmune tubulointerstitial nephritis Autoimmune glomerulonephritis
Joint (articular surface)	Mouse (DBA), rat, rabbit	Rheumatoid arthritis
Liver (hepatocytes)	Mouse	Chronic active hepatitis
Testes (spermatozoa)	Mouse (C57 black)	Autoimmune orchitis
Heart (myocardium)	Guinea pig, mouse	Autoimmune myocarditis
Thrombocytes	Rat (BN)	Idiopathic thrombocytopenia
Erythrocytes	Mouse	Autoimmune hemolytic anemia
Neuromuscular junction	Rat, guinea pig	Myasthenia gravis

to study genetic influences on autoimmune susceptibility. As might be expected, strong major histocompatibility complex (MHC) influences have been observed in some models as, for example, in mouse thyroiditis and experimental autoimmune encephalomyelitis (EAE) in rats. However, this does not seem to apply to the mouse antierythrocyte/anemia model mentioned above, although non-H2 genetic associations are evident.

One major disadvantage of this procedure is that the pathological effects induced are often transient in nature, presumably due to the imposition of autoimmunity on the normal animal with intact immunoregulatory feedbacks. As a consequence, overt clinical disease is not observed in many immunization models, even though short-term tissue infiltration is readily apparent histologically. However, EAE is a notable exception in that severe nervous signs can be readily induced by immunization of susceptible animals with myelin basic protein or its peptide derivatives. Clearly, the nervous system is more sensitive to the effects of immunological attack and these are more apparent clinically than, for example, those involving the endocrine tissues.

Although the relapsing form of EAE can be induced in guinea pigs by this method, in most experimental systems autoimmunity is rarely reactivated even by further immunization. There is evidence in a number of models that this effect may be due to the generation of antigen specific 'suppressor' cells, as demonstrated by adoptive cell transfer stud-

ies. Evidence for such activity has been found in mouse thyroiditis, mouse antierythrocyte autoimmunity and EAE in rats.

Although the injection of autoantigens in adjuvant can clearly have little relevance to the natural triggering events leading to human autoimmune disease development, immunization models continue to provide a wealth of information on many other aspects of autoimmunity. Currently, with the rapid accumulation of information at the molecular level concerning the subcellular components involved in autoimmunity, this procedure is likely to be utilized as a requisite step in the evaluation of purified recombinant polypeptides derived from such structures as potential B or T autoepitopes.

2. Induction of autoimmunity by impairment of immunological function ('immune depletion models')

It is now accepted that partial impairment of normal immunological function can lead to the onset of autoimmune reactivity, particularly of the organ-specific type. The earliest evidence in this context was the observation that thymectomy of certain mouse strains leads to the appearance of antinuclear antibodies. However, this relationship was firmly established in 1973 by two groups who independently reported the induction of organ-specific autoimmunity by procedures causing partial immunodepletion. Penhale and coworkers found that autoimmune thyroiditis could be induced by thymec-

tomy of 3-week-old Wistar rats followed by repeated low-dose irradiation. In a similar vein, Nishizuka and colleagues made the observation that thyroiditis spontaneously developed in mice following thymectomy alone, provided that this was carried out in the neonatal period. The autoimmune basis of these conditions was evident from the presence of infiltrating lymphocytes in the target tissue, circulating tissue-specific autoantibodies and the ability to transfer the disease to naive recipients with lymphocytes from affected animals. From 1975 onwards a number of other manipulations and treatments involving the immune system were shown to induce organ-specific autoimmune disease in rodents. A feature of all these procedures is either a deficiency of circulating T lymphocytes or their functional impairment as, for example, by a reduction in the range of the T cell receptor (TCR) repertoire. The spectrum of autoimmune diseases induced by this means is now impressive and includes diabetes, thyroiditis, gastritis, orchitis, oophoritis, prostatitis and coagulating adenitis. These conditions are rarely, if ever, seen in normal unmanipulated rodents of the same strains. The various depletion methods employed to induce these diseases are shown in Table 2.

A central question in understanding the process of autoimmunity is how the aberrant immune response is initiated. The development of immunodepletion models has been conceptually important in demonstrating the critical requirement for regulatory elements in the control of potential autoimmune reactivity in the normal individual. They also strongly suggest that neither aberrant antigen modification nor presentation are likely to be necessary antecedents of the autoimmune process. In consequence, they provide a powerful tool for studying the basis for the loss of self tolerance to peripheral self antigens and the development of destructive autoimmune lesions. In this regard they have proved particularly suitable for studying the immunological regulation of autoimmunity by reconstitution studies

using syngeneic lymphocytes derived from normal animals.

Immunodepletion models do not require immunization with putative autoantigens in adjuvant, as in the previous model above, but presumably involve the appropriate targeting of natural autoantigens rather than surrogate model antigens. In addition, they are also similar to their clinical counterparts in humans in that, once initiated, the disease is sustained and chronic. Furthermore, an association between various immunodeficient states and clinical autoimmunity in humans has been recognized. Because of these similarities in many pathological and immunological features they are providing invaluable insights into the pathogenesis of their human disease counterparts.

3. Induction of autoimmunity by infectious agents ('infection models')

The natural history of autoimmune disease in some individual patients strongly suggests the involvement of environmental or infectious agents in the inductive process. For example, postmeasles encephalomyelitis may result from an autoimmune response to myelin basic protein, and infection with Coxsackie virus group B has been associated with myocarditis in which there are autoantibodies to heart antigens. Despite this circumstantial evidence in isolated instances, direct evidence for the involvement of infectious agents in human autoimmune disease is unavailable. In contrast, experimental studies in animals provide some compelling evidence of the involvement of infectious agents, particularly viruses, in the triggering of certain forms of autoimmunity. Several viruses have been shown to induce diabetes-like conditions in inbred strains of mice with evidence of associated autoimmunity. Polyendocrine syndromes and diseases of nonendocrine organs have also been observed in certain infections. Certain bacteria or their products may also cause experimental autoimmune effects. For example, the injection of mycobacterial proteoglycan may induce arthritis, several bacterial products may similarly cause myasthenia (see below) and the injection of live *Listeria* directly into the testes can provoke an autoimmune orchitis.

The phenomenology of infection models require further investigation before a detailed understanding of their mechanisms can be gained and an autoimmune basis for their pathogenesis is unequivocally established. However, a number of immunological processes may underlie their pathogenicity, including:

1. The effect infectious agents have on host cells.

Table 2 Manipulations of the immune system leading to the development of organ-specific autoimmunity

<i>Experimental manipulation</i>
Combined sublethal irradiation/thymectomy of adult rodents
Neonatal thymectomy of rodents
Neonatal administration of cyclosporine in mice
Combined cyclophosphamide/thymectomy of adult rodents
High dose (42.5 Gy), fractionated total lymphoid irradiation of adult mice
Single-chain TCR transgenic mice
T cell transfer to syngeneic, T cell-deficient mice

Apart from the expression of virus gene products in persistently infected cells which may target them for host immune responses, virus may also have subtle effects on cell genes and the resulting enhanced or altered expression of host cell proteins could induce an autoimmune response. A further possibility is interaction of microorganisms with immunocompetent cells, leading to their polyclonal activation or reduced susceptibility to regulation. They may also cause a loss of function of regulatory cells with autoimmune consequences.

2. Molecular mimicry. Partial sequence homology between microbial antigens and self determinants may lead to the generation of host-specific responses by T helper cell bypass.
3. Idiotype-anti-idiotypic interactions (see below).
4. Tissue injury induced by infection may lead to the breaking of tolerance to self antigens and subsequent perpetuation of injury by autoimmune mechanisms. This mechanism could account for the induction of autoimmune disease by an acute, nonpersisting infection.
5. Enhanced expression of MHC antigen by microbial influences directly on the target cell or indirectly via lymphocytes.

4. Induction of autoimmunity by chemical agents ('chemically induced models')

A number of chemical substances appear to give rise to autoimmune effects in patients after prolonged use as therapeutic agents; for example, methyl dopa may cause a Coombs'-positive hemolytic anemia. Similarly, in the experimental context, several chemical agents have been shown to induce autoimmune-like syndromes, such as streptozotocin-induced diabetes in mice and mercuric chloride-induced glomerulonephritis in brown Norway rats. There are several possible mechanisms whereby chemicals may be involved in generating autoimmune manifestations, including: 1) modification of tissue components, particularly cell membrane structures; 2) breaking of self tolerance following liberation of cellular constituents by direct tissue damage; and 3) modification of immune function, particularly affecting regulatory cells. In general, withdrawal of the chemical agent results in recovery and diseases induced by this means have few clear analogies with naturally occurring human disorders. Low dose streptozotocin-induced diabetes mellitus in mice is a possible exception to the above statement, although the actual pathogenesis, whether direct toxicity or true autoimmunity, is still in doubt.

5. Induction of autoimmunity by anti-idiotypic (Id) responses ('anti-idiotypic models')

Theoretically, several mechanisms of induction of autoimmunity through Id interactions appear to be possible, although few examples of such are currently documented and none established as regularly utilized models for inducing autoimmunity. First, an anti-Id antibody may resemble an autoantigen sufficiently to be cross-reactive. This is exemplified in the insulin system, where it has been found that an antibody to the Id of anti-insulin antibody may interact with and actually trigger insulin receptors. Another, more dramatic example of the same mechanism appears to be the myasthenia gravis-like syndrome observed when rabbits are injected with a synthetic agonist (Bis Q) of the acetylcholine receptor. A second way in which the Id network can stimulate autoimmunity is through the development of 'parallel sets'. These may arise when immunologically distinct antibodies share a 'public' idiotypic. As an example, extensive idiotypic has been discovered between the antibodies to the acetylcholine receptor and the DEX antigen (1,3-dextran) present on the surface of many bacteria. Thus, the injection of such bacteria may induce autoantibodies to the receptor and hence myasthenia gravis. It may be no coincidence that many examples of autoimmune anti-Id effects involve receptor molecules.

6. Induction of autoimmunity by genetic manipulation ('transgenic models')

Transgenic technologies have provided new opportunities for developing animal models of autoimmune diseases. To date their development has been largely directed at obtaining new insights into the fundamental questions of autoimmunity, such as the nature of self tolerance, rather than the provision of relevant models of human disease. Expression of well-defined molecules can be induced in specific cell types by this technology and three broad approaches have been utilized to study aspects of autoimmunity:

1. The genes selected may code for a normally foreign antigen which will be synthesized at a particular development stage and behave essentially like a self antigen. The gene may be linked to a tissue-specific promoter which ensures its expression in a particular tissue while simultaneously avoiding thymic expression. Thus it is possible to generate cells expressing a genuine self molecule without concurrent thymic deletion of the complementary lymphocytes.
2. The genes selected may be rearranged T cell receptor or immunoglobulin genes coding for recognition molecules with specificity for a self

component. This procedure has the potential to generate antiself lymphocytes at high frequency, allowing the fate of such cells to be followed during and after ontogeny. Alternatively, the TCR repertoire can be greatly restricted by introducing the gene coding for an irrelevant nonself specificity. Thus the T cell compartment can be functionally depleted, leading to autoimmunity (see method 2 above).

3. The transgene may code for MHC molecules in order to address the question of the significance of their upregulation on target tissues during autoimmunity. This has led to the surprising finding that diabetes of nonimmune origin can be induced by overexpression of these molecules on the islet β cells. This is presumably due to derangement of cell metabolism as a consequence of high class II expression.

These strategies can also be combined to produce multiple transgenic animals in which, for example, an antigenic molecule can be directed to a specific cell type and the complementary TCR introduced into lymphocytes simultaneously.

The β cell of the pancreatic islet currently appears to be the most popular location for transgenic modification. Apart from the importance of type I diabetes as a human autoimmune syndrome, this cell is particularly convenient in that the transgene can be linked to the specific promoter for insulin production. Studies with transgenically modified β cells have been revealing in a number of respects. For example, experiments with lymphocytic choriomeningitis virus (LCMV) glycoprotein antigen expression on these cells point to immunological ignorance rather than tolerance as the mechanism responsible for the absence of reactivity to islet cell antigens, as diabetes does not occur spontaneously in this model and can only be induced by subsequent infection with LCMV. Furthermore, a number of additional lines of evidence indicate strongly that the virus is not breaking immunological tolerance in this experiment. New generations of these transgenic models are likely to revolutionize our understanding of this central phenomenon of autoimmunity.

Conclusions

Study of human autoimmune disease presents the considerable problem of deciding whether the changes observed are the cause or consequence of the disease process. The use of animal models avoids this difficulty and their manipulative potential has yielded many valuable insights into the autoimmune process. The disease range of induced models now available covers a wide spectrum of human autoimmune diseases and, although differing in detail from the human conditions, they have been instrumental in clarifying basic pathogenic mechanisms and, perhaps more importantly, in demonstrating that multiple and converging pathways to autoimmune disease development exist. They have also demonstrated that, in addition to a specific triggering event, disturbances of normal regulatory function may be prerequisite for chronic, sustained autoimmunity.

Finally, despite the multifactorial nature of autoimmune disease clearly revealed by modeling, this approach also offers the prospect that autoimmune disease might be controlled by interfering with the final common pathways without necessarily eliminating all the antecedent immune abnormalities.

Now as ever, autoimmune diseases constitute one of the main unsolved problems in human clinical medicine. This is because our knowledge of their etiology and pathogenesis is still not sufficient to provide new concepts towards specific therapy. They are considered to be pathological consequences of immune reactions directed towards autologous antigens.

Over 30 years ago, Witebsky and Milgrom formulated their well-known criteria for autoimmune diseases, the most important of which are that: 1) antibodies or lymphocytes specifically reacting with a defined autoantigen can be detected; 2) immunization of animals with an autoantigen results in an autoimmune disease corresponding to its original tissue distribution, and 3) experimental autoimmune disease is inducible in healthy recipients by passive transfer of autoreactive antibodies or lymphocytes. These postulates, essentially still valid today, pointed to the importance of animal models, and our present knowledge about etiopathogenesis is indeed mainly derived from the study of animals, in which autoimmune diseases are either experimentally induced by immunization with autoantigen, or occur spontaneously at high incidence.

Autoimmune diseases are a heterogeneous group of diseases. According to manifestation we can distinguish systemic diseases affecting various different tissues from organ-specific diseases, where the autoimmune process is restricted to single organ systems. There is good evidence that these two types differ considerably in etiology and pathogenesis.

Breakdown of autotolerance

The ability to tolerate autologous antigens, a central feature of the adaptive immune system, is guaranteed in redundant ways at the level of both the B and T lymphocyte system. It is thought to be the result of negative selection within the central lymphoid organs, i.e. bone marrow and thymus, where sensitive stages of developing B (sIgM⁺ sIgD⁻) or T (CD4⁺ CD8⁺) cell clones are eliminated by apoptosis due to high-affinity binding to autologous antigens. Autoreactive cell clones that escape these central selection processes for whatever reason are effectively controlled in their reactivity in the periphery, either passively by virtue of insufficient costimulatory signals or by active suppressive immunoregulation. These peripheral mechanisms are not specific for autoantigens, but are identical to those that

induce tolerance against any given foreign antigen. With regard to autoimmunity the interest has focused primarily on T lymphocytes, because of the central regulatory role of T helper cells in the immune response against protein antigens, and in view of the well-known association of autoimmune diseases with major histocompatibility complex (MHC) alleles differing in effectivity of antigen presentation to T cells.

Defective differentiation

According to the aforementioned concepts a breakdown in autotolerance can occur due to failures in thymic selection, and any factors that influence the survival of thymic lymphocytes could principally be expected to result in shifts in the peripheral T cell repertoire. As MHC molecules play an important role in the presentation of thymic autoantigens, changes in thymic selection may be one mechanism by which genes of the MHC influence autoimmune diseases. Nevertheless, it has to be stated that experimental data directly proving the occurrence of autoimmune reactions as a consequence of a disturbed intrathymic differentiation are lacking as yet.

Based on the finding that autoreactive lymphocytes of patients and experimental animals with organ-specific autoimmune diseases exhibited a limited number of V genes, it was debated whether autoimmunity may be the result of an abnormal immunoglobulin (Ig) or T cell receptor (TCR) repertoire. However, restriction fragment length polymorphism (RFLP) analysis performed in humans with autoimmune diseases did not indicate associations to certain Ig or TCR genes, and no consistent differences were detected in germline Ig genes of autoimmune mouse strains.

Peripheral loss of autotolerance

As to peripheral mechanisms, the loss of anergy against autoantigens may be the result of abnormal activation of T cells by antigen-presenting cells (APCs), such as dendritic cells, macrophages and B cells, that increase the expression of costimulatory surface molecules as a result of irritation, e.g. in the course of infections or local inflammatory reactions. In accordance with this notion is the established fact that the induction of experimental autoimmune diseases in animals requires immunization with autoantigens together with strong adjuvants that lead to

activation of APCs. Also, nonprofessional APCs, such as epithelial cells, may lead to local activation of autoreactive T cells by virtue of inappropriate expression of immunostimulatory molecules, such as MHC class II determinants. Another strong indication for a crucial role of T cell activation comes from results proving that enhanced levels of interleukin-2 (IL-2) are able to abrogate a state of anergy against tissue autoantigens. Further peripheral mechanisms, not related to T cell activation, may be a resistance of lymphocytes to apoptosis as described in the MLR-*lpr/lpr* mouse with systemic lupus erythematosus (SLE) symptoms and a defect in the expression of the fas apoptosis gene. However, no such association has been found in human SLE patients.

Peripheral tolerization of B lymphocytes results from antigenic stimulation without proper T cell help. Thus, a stimulus from autoreactive T helper cell clones may end the state of B cell autoanergy. Alternatively, certain foreign antigens may exhibit shared epitopes with autoantigens, and T helper cells specific for these shared epitopes may drive autotolerant B cells into activation.

Immunological cross-reactions between foreign microbial antigens and autoantigens are well known to be able to elicit humoral or cellular autoimmune responses, the classical example being rheumatic fever due to a 'normal' immune response against streptococcal antigens that is cross-reactive with myocardial protein. More recently, mycobacterial heat shock protein (hsp65) has gained interest as an antigen of possible relevance to pathogenic autoimmune responses in several diseases, including atherosclerosis.

Polyclonal, antigen-independent lymphocyte activation has been implicated in the activation of autoreactive lymphocytes and elicitation of autoimmune responses. Injection of mice with bacterial lipopolysaccharide (LPS), which is a polyclonal B cell activator in mice, has been shown to lead to the production of autoantibodies of various specificities. Even though these antibodies, due to the lack of T cell help, are of low affinity and nonpathogenic, the polyclonal B cell activation by 'LPS-like' bacterial substances may be at least one of the reasons for the close association of autoimmune and infectious diseases. Similarly the binding of bacterial superantigens to certain V_{β} chains of the T cell receptor has been discussed as a possible mechanism of autoimmunity at the T cell level. Finally, autoimmune phenomena are observed in the course of graft-versus-host reactions, supposedly due to polyclonal B cell activation induced by alloactivated donor T helper cells.

A disturbed balance in helper and suppressor influences exerted by T regulator cells has long been implicated in the pathogenesis of autoimmune diseases. While the classical T helper/suppressor cell model was abandoned several years ago, it is now thought that the balance between T helper1 (T_H1) and T helper2 (T_H2) cells is relevant to the maintenance of autotolerance, whereby T_H2 cells under normal conditions are thought to keep autoreactive effector T_H1 cells in line. Accordingly, quantitative or functional abnormalities in this balance may allow autoimmune reactions to occur. Investigations of joint lesions in rheumatoid arthritis (RA) patients seem to support this concept, as cloning studies identified the vast majority of infiltrating T cells as belonging to the T_H1 subtype, whereas T_H2 clones were only rarely found. In contrast, synovial specimens from more benign, nondestructive types of arthritis were found to contain high levels of IL-4 mRNA. From this it was concluded that the local presence of functional T_H2 cells may be critical for the self-limitation of the autoimmune process in the affected joints.

Besides their central roles in the effector phase of autoimmune processes (see below) cytokines are certainly critically involved in systemic and local immunoregulation and thereby modulate the clinical outcome of an autoimmune disease. Furthermore, the above mentioned data on IL-2 suggest that they may also take part in the breakdown of self-tolerance. Recently, enhanced systemic levels of inflammatory cytokines (IL-1 β , IL-6, tumor necrosis factor α (TNF α)) and soluble cytokine receptors (sIL-2R, sTNFR) were reported to significantly correlate with the clinical activity of RA in children, whereby the different clinical subtypes displayed different patterns.

Effector mechanisms

As to effector mechanisms, autoimmune diseases are no different from any other pathogenic immune response against foreign antigens involving reactions of types II (cytotoxic antibodies), III (immune complexes), IV (cellular-mediated immunity) and V (stimulating antibodies) according to the Gell/Coombs nomenclature. Furthermore, antigen non-specific mechanisms secondarily activated by autoantigen-activated lymphocytes play an important pathogenetic role.

The role of autoantibodies

The detection of circulating and/or tissue-bound autoantibodies is undoubtedly one of the most consistent findings in autoimmune diseases in human

and animal models. Although low levels of autoantibodies can be detected in healthy individuals, and, on the other hand, autoimmune diseases can exist without detectable autoantibodies, there is in general a good correlation between peripheral levels of autoantibody and activity of an autoimmune disease, whereby the spectrum of specificities may be characteristic, sometimes even diagnostic, for a particular autoimmune disease. There are several ways by which autoantibodies can be involved in the pathogenesis of autoimmune diseases:

- Tissue-specific autoantibodies may activate complement and lead to cytolysis of the target cell (type II), as is observed for example in spontaneous or drug-induced autoimmune lysis of red or white blood cells. In organ-specific diseases cytotoxic autoantibodies are thought to contribute to tissue destruction, e.g. in autoimmune diseases of endocrine glands, in Goodpasture's syndrome and in myasthenia gravis.
- The binding of autoantibodies to tissues leads to triggering of the natural immune system by attracting and activating Fc receptor and complement receptor bearing cells to phagocytosis, cytotoxicity and antibody-dependent cellular cytotoxicity. Furthermore, the amplification system of inflammatory mediators involving the clotting fibrinolysis and kallikrein-kinin systems can be induced by autoantibodies and complement via activation of factor XII.
- Autoantibodies specific for cell surface structures, e.g. hormone receptors, can stimulate or block the growth and functions of target cells. Stimulatory autoantibodies were first recognized in autoimmune disease of the thyroid gland being directed against the thyroid-stimulating hormone (TSH) receptor, blocking autoantibodies are found for example in myasthenia gravis, and bind specifically to the motor end-plate.
- Autoantibodies specific for soluble cell products can give rise to high levels of circulating immune complexes (type III reactions) causing inflammatory tissue damage at the sites of deposition as seen in both systemic and organ-restricted autoimmune diseases. The localization of immune complexes is dependent on hemorheological factors, Fc binding, and on nonspecific binding characteristics of certain tissues. Hence, an enhanced binding of DNA to basement membranes appears to be responsible for the characteristic deposition of DNA-anti-DNA complexes.
- Autoantibodies with specificity for the idiotype of autoantibodies have been detected in several auto-

immune diseases. Treatment with such autoantibodies has been shown to suppress spontaneous autoimmune disease in animal models, which points to the potential of these autoantibodies to control the course of an autoimmune disease. On the other hand, as anti-idiotypic antibodies can mimic the primary antigen (i.e. autoantigen) autoantibodies could enhance autoimmune disease by eliciting and/or perpetuating an autoimmune response.

The role of T cells

For a long time autoantibodies were thought to play the major role in autoimmune effector mechanisms. Results in both experimental and spontaneous animal models, however, revealed that autoreactive T lymphocytes are both necessary and often sufficient to cause autoimmune disease. This was shown for example in the obese strain of chickens afflicted with spontaneous Hashimoto-like thyroiditis, where eradication of the T cell system by neonatal thymectomy plus treatment with T cell-specific antibodies resulted in prevention of disease. On the other hand, it was shown that the disease could be effectively transferred to healthy recipients of the same genetic background by injection of autospontaneous thymocytes, or purified T cells derived from infiltrated thyroid glands of B cell-depleted (bursectomized) obese strain chickens. The dominance of the autoreactive T effector cell also emerged from the work on experimentally induced autoimmune diseases in rats and mice, where autoantigen-specific T cell lines could be developed that were instrumental in the study of the pathogenetic role of T cell immunity. Transfer of low numbers of viable autoreactive T cells induces vigorous autoimmune disease in several models. If such cells are growth arrested by irradiation prior to transfer, the recipient becomes protected against induction of the disease by immunization with the autoantigen. Taken together, these data clearly point to the fact that both the induction and effector phases of an autoimmune disease can primarily involve autoantigen-specific T lymphocytes. The appearance of autoantibody may often be secondary and have only a modulatory role in the disease.

As to the effector mechanisms by which autoreactive T cells mediate tissue damage, the evidence obtained suggests that it is mainly the CD4⁺ T_H1 phenotype (T_{D1H}) that upon activation by autoantigen in the context of MHC class II molecules releases cytokines, such as IL-2, IFN γ , TNF α/β and others, and which by themselves or by activation of other specific (autoreactive CD8⁺ cells) and nonspecific (NK cells, macrophages) inflammatory cells destroy the target tissue. T_H2 cells, as mentioned above,

supposedly suppress T_H1 effector cells, but, on the other hand, may exert helper functions to autoreactive B cells via IL-4, IL-5, IL-6, and may keep autoreactive T cells alive by IL-10, which – besides its immunosuppressive effects – prevents apoptosis.

Nonspecific mechanisms

Pathogenetic mechanisms of natural immunity were long ago recognized as important in autoimmune disease. This is confirmed by a number of more recent investigations showing the crucial roles of inflammatory monokines IL-1 β , IL-6, and particularly of TNF α , as well as several chemokines in autoimmune tissue destruction. Furthermore, IL-12 produced by several professional antigen-presenting cells has been shown to be critical in the development of autoimmune disease, as it promotes the differentiation of T_H1 cells. The essential role of the monocyte/macrophage series is further underscored by more recent findings in certain animal models, where autoimmune diseases were effectively controlled by antioxidants or by inhibition of nitric oxide synthesis. Until recently, it was thought that nonspecific effector cells were secondarily activated by autoantibodies, autoimmune complexes with or without activation of complement, and cytokines derived from activated T helper cells. The newer concepts of how autotolerance can get lost in the periphery (see above), however, make it likely that a primary abnormal activation of monocytes/macrophages may lead to loss of autotolerance and thereby initiate an autoimmune disease. This view is supported by recent data in the obese strain of chickens with spontaneous autoimmune thyroid disease, and by the induction of lupus-associated autoantibodies in BALB/c mice by i.p. injection of pristane.

It should be stressed that the tissue destruction process in autoimmune diseases with few exceptions has to be regarded as the result of a combination of several humoral and cellular pathogenetic mechanisms.

Modulating factors in autoimmune disease

In discussing factors or conditions that can modify the severity and course of autoimmune disease a clear distinction between etiology and pathogenesis becomes often difficult. This is due to the fact that autoimmune diseases have a multifactorial etiology requiring both genetic features and environmental conditions to occur. The question as to whether a given genetic or epigenetic factor is permissive to an

autoimmune disease or only modifying the pathogenesis is open in most cases.

Genetic predisposition

The first evidence for an involvement of certain genes in the development of autoimmune diseases came from clinical experiences in humans revealing familial incidence of certain autoimmune diseases. This was confirmed by the observations that certain strains of experimental animals spontaneously exhibit enhanced frequencies of certain autoimmune disorders, and that selective breeding for the autoimmune phenotype resulted in further enhanced incidence and severity. The best-established animal models for spontaneous autoimmune diseases are strains of mice with manifestations of systemic lupus erythematosus, and the obese strain chickens afflicted with an organ-specific disease, i.e. autoimmune thyroiditis. Also the susceptibility to the induction of experimentally induced autoimmune disease has been shown to be genetically determined.

Various loci have been found to be involved in the development of autoimmune diseases, some of them are associated with the major histocompatibility complex (MHC). The best example for the association of an autoimmune disease with a certain MHC allele is HLA-B27, which confers an 85–90-fold relative risk of ankylosing spondylitis. Further examples include rheumatoid arthritis associated with HLA-DR4 and insulin-dependent diabetes mellitus (IDDM), with HLA-DR4 and DR3. In the latter it was shown that a certain allele, i.e. HLA-DR2, confers protection with a relative risk of 0.2. Mechanisms that are discussed to explain MHC associations of autoimmune diseases include 1) insufficient thymic presentation of autoantigens, 2) abnormal presentation of autoantigens to peripheral T helper cells, 3) association with alleles of non-MHC loci, such as the genes for TNF α/β , that map to the MHC and are linked with certain MHC alleles, and 4) antigenic mimicry between microbial antigens and autologous MHC molecules.

Another set of genes – not associated with the MHC – is involved in different mechanisms of immunoregulation, and, finally, the susceptibility of the respective target organ in organ-specific autoimmune diseases appears also to be under genetic control. The latter two types of genes have been defined by classical genetic analysis of experimental and spontaneous autoimmune diseases in animal models.

Endocrine and neuroendocrine influences

Immune responses in general are not only regulated by mechanisms intrinsic to the immune system, but also by endocrine and neuroendocrine signals. It has

long been recognized that many autoimmune diseases preferentially occur in females, whereas males appear protected probably due to immunosuppressive properties of androgens. Similar observations were made when obese strain chickens were first developed. However, with continuous selective breeding this sex difference disappeared, which suggests that sex hormones only have a modifying role in this disease.

Hormones involved in stress responses, such as glucocorticoids, catecholamines, endogenous opiates and most of the anterior pituitary hormones, have strong effects on specific and natural immune functions. It is well known that acute or chronic stress can exacerbate certain autoimmune diseases in humans. Chemical sympathectomy (by means of 6-OH-dopamine) has been shown to influence the course of experimental autoimmune disease in animals. Obese strain chickens were found to have enhanced plasma levels of corticoid-binding globulin leading to a diminished availability of free glucocorticoids. Early *in vivo* supplementation with free corticosterone prevented the onset of thyroiditis. Further to this, obese strain chickens were shown to have a central defect in the responsiveness of the hypothalamo-pituitary-adrenal axis to signals of the activated immune system, resulting in the lack of the peripheral glucocorticoid response after immunization as it is observed in healthy controls, and it was concluded that the defect in this negative feedback may predispose to autoimmunity. Findings in two experimentally induced models, i.e. experimentally induced encephalomyelitis and experimentally induced arthritis in rats, strongly supported this concept, and there is now good evidence that human patients suffering from rheumatoid arthritis show endocrine abnormalities indicating altered pituitary functions, which may contribute to etiology and/or pathogenesis of the disease.

Age

Aging is known to be associated with increased autoimmune phenomena. However, these increased 'forbidden' responses as manifested in mildly elevated levels of autoantibodies are not necessarily pathogenic. Some authors have assigned this age-associated autoimmunity even a physiological role as a possible scavenger mechanism for cell and tissue constituents that accumulate due to enhanced tissue damage at higher age. Most of the acute severe autoimmune diseases usually start at young to middle ages, only certain chronic processes, e.g. chronic polyarthritis, tend to severe at higher ages.

Environmental influences

Little is known about environmental influences on autoimmune disease. In general, any exogenous agent or condition that affects the immunogenic properties of autoantigens and/or the regulation of the immune response can be expected to modify autoimmune diseases. Modification of autoantigens and/or immune reactivity can occur by several bacterial and viral infections, and the outbreak of several autoimmune diseases indeed appears to be associated with certain infectious diseases, such as IDDM or multiple sclerosis following certain viral infections. Another way by which bacterial or viral infections may induce autoimmune disease is the abovementioned antigenic cross-reaction with autoantigens.

Autoimmune diseases as side-effects of drugs comprise type II reactions against drug-modified autologous white or red blood cells, but also lupus-like phenomena in patients taking β -adrenergic blockers or drugs like hydralazine and procainamide. While the mechanism(s) of action of β -blockers in this respect is not clear, *in vitro* investigations have shown that hydralazine and procainamide induces self-reactivity in cloned, heteroantigen-specific T cell lines by DNA methylation. This suggests that DNA methylation as a mechanism of gene expression plays a role in the specificity of immune responses, and that drugs or substances that interfere with the regulation of gene expression in general may have the potential to induce forbidden immune responses leading to autoimmune disease.

AUTOIMMUNE DISEASE, SPONTANEOUS ANIMAL MODELS

Georg Wick and **Roswitha Sgonc**, Institute for General and Experimental Pathology, University of Innsbruck, Innsbruck, Austria

Guido Kroemer, Centre National de la Recherche Scientifique – UPR 420, Villejuif, France

Autoimmune diseases can be experimentally induced by immunization of normal animals with the respective antigens combined with appropriate adjuvants. By this means organ-specific experimental autoimmune diseases can be produced in animals of many different strains and in nearly every organ. There is no doubt that such experimentally induced autoimmune diseases, e.g. experimental allergic encephalomyelitis (EAE) or experimental autoimmune thyroiditis (EAT), have contributed considerably to our understanding of the pathogenesis of autoimmune diseases in general and these models in particular. It is, however, also clear that most of these artificially produced autoimmune diseases often do not parallel their human counterparts with respect to all essential characteristics.

Fortunately, there are several animal strains available that – based on many years of selective breeding – develop certain organ-specific or systemic autoimmune diseases spontaneously, i.e. without any experimental manipulation. These models mimic the human situation much more closely and thus serve as apt objects of study for the pathogenetic mechanisms underlying the development of these diseases as well as the establishment of new diagnostic and therapeutic strategies. In this entry, spontaneous animal models for four types of diseases, two systemic and two organ specific, will be presented. This selection

is based on the large body of literature on these models, but it should be emphasized that several other promising strains exist which have not yet been investigated in such depth but may also turn out to be very useful in the future, such as the Buffalo (BUF) rat that develops an autoimmune thyroiditis in high frequency, the autoimmune glomerulonephritis, arthritis and orchitis emerging in Aleutian minks, the delayed amenalosis (DAM) chicken with autoimmune depigmentation, and several others.

In principle, spontaneous autoimmune models arose due to a combination of serendipity (spontaneous mutations causing autoimmune phenotypes) and inbreeding plus selection procedures. As a consequence, inbred animal strains afflicted by spontaneous autoimmune diseases usually manifest disease phenotypes that are compatible with breeding programs, i.e. that do not cause severe pathology before animals reach sexual maturity, although they sometimes may need special dietary, hormonal, etc. supplementation. Alternatively, autoimmune phenotypes are studied in severely diseased F1 crosses of relatively normal parental inbred strains. This particular feature of spontaneous autoimmune disease models may explain why certain laboratory-produced mutations (e.g. disruption of the CTLA4 gene) that give rise to an acute, fulminant autoimmune disorder have not been observed spontaneously.

Spontaneous animal models for organ-specific autoimmune diseases

Obese strain of chickens as an animal model for Hashimoto's thyroiditis

During the first few weeks after hatching, obese strain (OS) chickens develop a hereditary spontaneous autoimmune thyroiditis (SAT) that resembles human Hashimoto's disease in all clinical, histopathological, endocrinological and immunological aspects. The thyroid glands of OS chickens become heavily infiltrated by mononuclear cells, finally resulting in complete destruction of their architecture entailing clinical symptoms of hypothyroidism (Figure 1), such as small body size – albeit with relatively high body weight due to the deposition of subcutaneous and abdominal fat – lipemic serum, long silky feathers, cold sensitivity, low laying capacity, diminished fertility and poor hatchability. In common with Hashimoto's thyroiditis, the infiltrated thyroid glands show high numbers of well-developed germinal centers as a characteristic hallmark that is unique to this model and absent in EAT. The serum of OS chickens contains autoantibodies to thyroglobulin (Tg-AAb), to thyroid microsomal antigens (MSAs) and to tri-iodothyronine (T_3) and thyroxine (T_4). The hypothyroid symptoms can be prevented or reversed by appropriate supplementation of the diet with thyroid hormones.

The infiltrated thyroid gland itself has been identified

as a major Tg-AAb producing organ and complement-binding Tg-AAbs are also vertically transferred from the mother hen via the egg yolk into the newly hatched chick. The main initial effector mechanism for the development of SAT is, however, the infiltration by interleukin-2 receptor (IL-2R)⁺ CD4⁺ T cells, and Tg-AAbs only play an accelerating role.

OS chickens also develop autoantibodies against a variety of nonthyroid organ-specific or systemic autoantigens, but without concomitant histopathological or functional lesions. Adoptive transfer experiments have shown that thyroid-infiltrating lymphocytes are most effective in transferring the disease into histocompatible recipients of the Cornell C strain (CS), the nearly normal mother strain from which the OS was originally developed by R.K. Cole by selective breeding. Functional studies revealed a general hyperreactivity of the OS immune system against autoantigens, but also against exogenous antigens, such as sheep red blood cells and Rous sarcoma virus-induced tumors, as well as the T cell mitogens concanavalin A (con A) and phytohemagglutinin (PHA). This hyperreactivity is paralleled by a significantly increased production of IL-2 by OS peripheral blood lymphocytes and spleen cells compared with normal controls.

OS macrophages also show signs of hyperreactivity, such as an increased oxidative burst activity. Coculture experiments combining thymocytes and autologous peripheral blood lymphocytes revealed a

Figure 1 Normal White Leghorn chicken (left), and 6-month-old female OS chicken (right). Note the smaller size and the long silky feathers of the OS bird.

defect of the suppressive activity in the OS thymus that contributes to the general immunological hyper-reactivity in this strain.

Furthermore, OS chicken thymocytes are relatively resistant against glucocorticoid-induced thymocyte apoptosis, even if high pharmacological doses are applied. This phenomenon may be involved in the inefficient thymic negative selection process in this strain, leading to insufficient deletion of auto-reactive clones.

In addition, factors extrinsic to the immune system that also affect immunoregulation are altered in OS chickens, such as a significantly increased serum concentration of corticosteroid-binding globulin (CBG) and, therefore, decreased free, metabolically active glucocorticoids. Furthermore, OS chickens show a malfunctioning immunoendocrine feedback loop: injections of antigen or IL-1 do not lead to the surge of blood corticosterone levels observed in normal birds. This altered glucocorticoid response is due neither to a defective production of glucocorticoid increasing factors (mainly IL-1) by the immune system of the OS, nor to a disturbed release of adrenocorticotrophic hormone (ACTH) by the pituitary, nor to insufficient responsiveness of the adrenal glands, but can rather be attributed to an altered responsiveness of the hypothalamus to glucocorticoid-increasing factors or of the pituitary to corticotropin-releasing hormone (CRH).

Transfer experiments and cross-breeding studies between OS and inbred normal chickens led to the assumption that *both* autoreactivity of the immune system and a genetically determined primary susceptibility of the target organ are prerequisites for the development of severe SAT.

Various functional abnormalities of OS thyroid glands, such as an increased ^{131}I uptake before the onset of infiltration, an autonomous thyroid function that cannot be suppressed by high doses of T_4 , and a decreased growth rate of OS thyroid epithelial cells *in vitro* with insufficient release of growth-promoting autocrine factors, can be demonstrated, but have not been found to be essential for the development of SAT. There is also no indication for an abnormal composition of OS thyroglobulin.

The question of whether there is a genetically determined primary aberrant expression of major histocompatibility complex (MHC) class II antigens on thyroid epithelial cells of OS chickens has not yet been unequivocally clarified. OS thyroid epithelial cells do, however, clearly show a lower threshold for interferon γ -induced MHC class II expression compared with those of normal chickens, a phenomenon that is restricted to the thyroid gland and cannot be

found with cell suspensions of other organs, such as the adrenal gland and the kidney.

Investigations on the putative role of viruses during the development of SAT led to interesting findings in two directions. First, C-type particles have been demonstrated electronmicroscopically in the thyroid gland of OS but not of normal chickens, and this indication for a possible presence of a thyrotropic virus has recently been corroborated by the demonstration of 2', 5'-adenylate synthetase in the thyroid, an enzyme that is induced by interferon γ and activated by double-stranded RNA. Second, parallel studies have led to the discovery of a new endogenous virus (*ev22*) locus that seems to be specific for the OS and the presence of which (in Southern blots of OS DNA digests) correlates significantly with the above-mentioned decreased corticosterone response to IL-1 or antigen. It is not yet clear if this latter observation has any pathophysiological significance.

OS chickens possess three MHC (*B*-locus in the chicken) haplotypes (*B5*, *B13* and *B15*) but each of the homozygous sublines carrying these haplotypes still segregates for other major and minor histocompatibility antigens. The haplotypes were found to have only a modulating effect on the severity and incidence of SAT.

Genetic analyses that were aimed at the identification of the number and nature of genes that possibly contribute to the development of SAT have led to the formulation of a hypothesis postulating the contribution of both essential and modulatory genes. From these studies it became clear that *one essential recessive autosomal 'thyroid susceptibility gene'* is a prerequisite for the development of SAT. So far, this gene or the product of it, has not been identified. Possible candidates for additional modulating, non-essential genes are those that regulate CBG levels and T cell hyperresponsiveness, those determining excessive macrophage function, the *ev22* locus which cosegregates with the altered corticosterone response to cytokines, the primary altered iodine thyroid metabolism, and MHC-linked immune response genes.

Finally, it should be mentioned that the OS model has proven to be of great value for the assessment of new immunosuppressive drugs, such as synthetic androgen analogs that possess immunosuppressive and anti-inflammatory properties but are devoid of undesired endocrinological side-effects.

Animal strains with spontaneous insulin-dependent diabetes mellitus (IDDM)

Many animal species may be afflicted with spontaneous IDDM, but so far only two inbred models

of IDDM have been subjected to detailed immunological and genetic analysis: the nonobese diabetic mouse (NOD) mouse and the diabetes-prone biobreeding (DP-BB) rat. In both cases the autoimmune etiology of IDDM has been clearly established based on histological (mononuclear cell infiltration of the islets of Langerhans before the development of clinically manifest diabetes) as well as functional evidence. DP-BB rats and NOD mice exhibit both humoral and cellular autoimmune responses against islet β cells, although the pathogenetically relevant antigens remain to be identified. Disease development is inhibited by immunosuppressive intervention (neonatal thymectomy, administration of cyclosporin A, monoclonal antibodies against CD4, class II molecules, or the IL-2R knockout of the β_2 -microglobulin gene) and autoimmune insulinitis and β cell destruction can be adoptively transferred to healthy histocompatible recipients by bone marrow or spleen cells from NOD or DP-BB donors. The role of T cells is further underlined by the predominance of T cells in infiltrated islets, the absence of diabetes in NOD nu/nu mice, and the efficient transfer of disease into B cell-deprived recipients. Recent studies on the cell type responsible for diabetes transfer indicate that CD4⁺ T_H1 but not T_H2 cells are responsible for β cell destruction, both in NOD mice and in DP-BB mice. Thus, autoimmune diabetes is a T_H1 disease. Whether T_H2-like cells may act as endogenous immunosuppressors is, however, still a matter of debate.

About 40% of male and 70% of female NOD mice develop overt IDDM at 7 months of age, whereas the DP-BB model lacks a female preponderance. Interestingly, a low percentage of DP-BB rats also develop autoimmune thyroiditis. Interindividual differences in the expression of disease may be attributed to unknown environmental factors or to the stochastic process of T cell receptor and antibody gene rearrangement which creates genetic heterogeneity between individuals with identical germline genes. Extensive studies have addressed the genetics of IDDM and the molecular defects implicated in the etiopathogenesis of the disease. In the NOD model, one dominant gene confers predisposition to lymphoid infiltration of pancreatic islets, whereas the development of manifest IDDM requires at least several further genes, one of which is linked to the NOD MHC. NOD mice lack messenger RNA transcribed from the I-E α gene and, consequently, do not express I-E products on the cell surface. Moreover, the NOD class III-A β chain is mutated in positions 56 and 57 of the first external domain. Expression of I-E α transgenes in NOD mice prevents insulinitis, whereas I-A β of a normal haplotype fails to do so, thus

underlining the importance of the I-E defect for IDDM development. In addition to the diabetogenic NOD MHC (termed *Idd1*), at least 10–14 different IDDM susceptibility loci (*Idd2* through *Idd14*) influence the incidence and the severity of insulinitis and diabetes. The best fitting model for these loci is a multiplicative (epistatic) model. Thus far, the pathogenic contribution of these loci remains elusive at the molecular level. It may be significant that one of the insulinitis susceptibility loci has been mapped close to the apoptosis-inhibitory oncogene *bcl-2*. Moreover evidence was obtained for linkage of *Idd3* with IL-2 and *Idd10* with IgG-Fc receptor polymorphisms. In the DP-BB rat, two recessive diabetogenic loci have been postulated. One of them (*Iddm2*) appears to be associated with the class II subregion of the MHC, the other (*Iddm1*) with a gene responsible for a profound T cell lymphopenia which may be caused by defects in prothymocyte differentiation and/or thymic antigen-presenting cells. The pathogenetic relevance of ectopic MHC class II expression on islet β cells is still a matter of debate, but experiments with transgenic animals carrying class II genes under the control of the insulin promoter suggest that the presence of such molecules on β cells *per se* is insufficient to initiate autoimmune insulinitis. In contrast, expression of the costimulatory molecule B7-1 markedly accelerates diabetes in transgenic NOD mice.

Spontaneous animal models with systemic autoimmune diseases

University of California at Davis (UCD) 200 strain as an animal model for progressive systemic sclerosis (SSc) – scleroderma

SSc is a human disease that is classified among the autoimmune connective tissue diseases that also comprise systemic lupus erythematosus (SLE), dermatomyositis and polymyositis, rheumatoid arthritis and several others. While there are several well-established, spontaneously occurring animal models available for SLE, models for the other conditions in this group are either nonexistent or of questionable significance. This is also true for SSc for which homologous disease of rats has been proposed as a model, as it is associated with chronic skin lesions with increased thickening and collagenization of the dermis. Significant titers of antinuclear antibodies (ANAs) are, however, lacking and the presence of immune complexes in vascular walls is also not characteristic for SSc. Another model for human scleroderma is the tight-skin (TSK) mouse, a dominant mutant of the inbred B10.D2 (58N/SN) mouse strain. The TSK mouse is characterized by cutaneous

and skeletal hyperplasia but – in contrast to human SSc – these animals do not show gastrointestinal involvement, particularly the characteristic vascular pathology. There is also no evidence in these mice of early mononuclear cell infiltration of the skin.

The UCD 200 chicken model, described below, has many more similarities with SSc than all the models described so far, but it has to be emphasized that there are also some dissimilarities, including the development of glomerulonephritis, particularly in older animals, that may, however, be a sequel of secondary infection.

The first (male) chickens showing signs of a genetically determined fibrotic disease resembling SSc were discovered in 1942 by P. Bernier at the Department of Poultry Husbandry, Oregon State University, Corvallis. These birds exhibited comb and dermal swelling accompanied by fibrosis. The affected birds were then selectively bred for over 40 years and a new strain, now denoted UCD 200, was developed where males and females are affected to about the same extent.

200 strain UCD chickens exhibit severe alterations of the comb, neck and extremities. The comb already becomes visibly swollen and red 1–2 weeks after hatching, and at the age of 4 weeks about 90% of all birds develop comb necrosis with subsequent resorption ('self-dubbing'). Similar events occur in the digits of 30–40% of the birds, again beginning at 2–3 weeks of age, including polyarthritis of peripheral joints. At 2–4 weeks of age the skin of the neck also becomes involved, but the constant mechanical irritation of the neck in the outlets of the cages to gain access to food and water may also contribute to the lesions at this particular location.

A mononuclear cell infiltration is first observed in the affected skin areas and can be demonstrated in about 70% of line 200 birds at 1 week of age. Mononuclear cell infiltration starts perivascularly and is followed by vessel occlusion, similar to one of the hallmarks of human SSc. This acute inflammatory process reaches a peak at 2 weeks of age and subsides at the age of 5 months, when no more skin inflammation can be shown macroscopically or microscopically. At 5 months of age the esophagus becomes involved with a severe cellular infiltration around vessels and in the lamina propria of mucous glands in about 50% of the animals, increasing to 70% or more at the age of 1 year. Similar changes can be observed in the lamina propria of the small intestine, albeit at a lower frequency of about 30%. Furthermore, mononuclear cell accumulations can be found in the lung, starting at 1 week of age (60%) and decreasing to about 30% at 4–6 weeks, in the heart

and kidney (30–40% at 5–6 weeks of age) and the testes, beginning at 4–6 weeks of age.

The early mononuclear cell infiltrates in the skin are composed mainly of T cells expressing the γ/δ receptor. An influx of α/β T cell receptor-positive cells is first observed later, i.e. at the age of 20 days. While γ/δ -positive T cells occur mainly in the upper layers of the dermis, α/β -positive cells prevail in the deeper areas. Most of these latter cells express B-L, the chicken MHC class II analog.

The vascular changes are very characteristic in UCD 200 birds and can be found in most of the organs mentioned above. They are first noted in the comb and the feathered skin at 1 week of age, where the vessels show hyperplasia of the media and intimal thickening. In the internal organs the vascular changes are found later but always precede the macroscopic and clinical symptoms.

The nature of the increased deposition has not yet been studied in great detail by chemical and molecular biological methods but only by immunohistology on frozen sections, using specific antibodies against the different collagen variants. With this approach an increase of type III and type VI collagens can be noted in the skin and the terminal vascular rarefaction becomes clearly evident when antibodies against basement membrane components, such as type IV collagen or laminin, are applied. The accumulation of connective tissue, as manifested by fibrosis of the lung, severe myocardial muscle fiber destruction, subpericardial fibrosis, thickening of the esophageal wall and effects on other internal organs, leads to the premature death of these birds. In addition, they are prone to secondary infections and show a low fertility rate due to the massive involvement of the gonads, particularly the testes.

As in the human disease, no gross alteration at the genomic level of collagen genes has been found by means of restriction fragment length polymorphism (RFLP) analysis, thus suggesting that the UCD 200 model is an appropriate counterpart for studying the altered collagen metabolism in SSc. Investigation of the putative role of endogenous viruses (*ev*) for the development of SSc led to the discovery of *ev23*, which is found only in UCD 200 chickens. So far, the role of *ev23* in the development of avian scleroderma is unclear.

Similar to human patients with SSc, sera from UCD 200 chickens contain ANAs in high frequency. At 1 month of age over 70% of the birds show ANAs with various staining patterns, including speckled centromeric and nucleolar fluorescence that are also characteristic of human SSc. These antibodies belong mainly to the IgY isotype, homologous to mam-

malian IgG, and can also be demonstrated on mammalian substrates, such as HEp-2 cells.

Although the UCD 200 chickens have now been kept for over 40 years, there are only a very few reports in the literature addressing the possible pathogenetic mechanisms leading to the SSc-like disease in this strain. The group of Gershwin and colleagues has shown that thymectomy on the day of hatching significantly reduces – but not completely abolishes – the comb/neck lesions, when assessed at the age of 8 weeks. Furthermore, the severity of the lesions in general was significantly reduced by this manipulation.

In vitro, UCD 200 peripheral blood T lymphocytes show a significantly decreased mitogen-induced proliferation associated with a decreased capacity to produce IL-2 and to express IL-2 receptors compared with normal White Leghorn chickens. In contrast to the deficient *in vitro* IL-2 production, the sera of UCD 200 chickens contain significantly higher levels of IL-2 bioactivity.

UCD 200 chickens also show a disturbed immunendocrine feedback, characterized by a prolonged secretion of corticosterone after application of certain cytokines. Although the peak serum concentrations of the glucocorticoids are equal to that of controls, UCD 200 have to secrete twice as much ACTH to achieve this corticosterone serum level, owing to an apparent hyporesponsiveness of the adrenal gland to this secretagogue. The altered cytokine-induced glucocorticoid secretion is found in early as well as in chronic, sclerotic stages of the disease.

Recent studies by Sgontz and coworkers brought forward an interesting aspect on the pathogenesis of SSc: simultaneous *in situ* analysis of frozen skin sections for apoptosis and immunofluorescence staining for cell markers show that endothelial cells are clearly the first cells to undergo apoptosis in the skin of UCD 200 chickens, a process that seems to be induced by antibody-dependent cytotoxicity. Endothelial cell apoptosis is found before any other macroscopical or microscopical alterations are visible. Analysis of early lesion skin biopsies from human SSc patients shows a similar course of events.

The UCD 200 chickens are homozygous for a variation of the MHC haplotype B17. In addition they have been typed for some of the other blood groups and found to carry A1, C2, D3, E7 and P2. They are homozygous for the immunoglobulin 7S Ig (homologous to mammalian IgG) allotype 1.7. Since UCD 200 chickens are still segregating at the B locus and some other major blood group loci, attempts have been made in recent years to develop a subline that matches one of the related inbred normal lines

(line 058) in order to allow for mutual cell transfer experiments. Such a subline, denoted line 206, carrying the B15 haplotype has now been established.

In summary, the UCD 200 line of chickens seems to provide the best model for human SSc available so far. It mimics most of the clinical, histopathological and immunological hallmarks of SSc, albeit in an accelerated fashion. With respect to more detailed further studies, particularly the development of new therapeutic strategies, this accelerated course of the disease is an experimental advantage.

Murine strains with SLE-like autoimmunity

Several models of spontaneous SLE in mice have been extensively studied, namely New Zealand Black [NZB], (NZB × New Zealand White [NZW])F1, (NZB × SWR)F1, BXSB, and MRL mice, which exhibit two forms of disease, a late-life variety appearing during the second year of life (male [NZB × W]F1, female BXSB, MRL/Mp-*+/+* of both sexes, NZB mice of both sexes) and an acute form beginning a few weeks or months after birth (female [NZB × W]F1, male BXSB, MRL/Mp mice of both sexes homozygous for the lymphoproliferation [*lpr*] gene, female and male [NZB × SWR]F1 mice). Accelerating factors are female sex hormones in (NZB × W)F1, a gene located on the Y chromosome (*Yaa* = Y chromosome-lined autoimmunity accelerator) of BXSB mice, the *lpr* gene in MRL mice, or genes from phenotypically normal SWR or minimally affected NZW mice in crosses with the NZB strain. All these models are characterized by hypergammaglobulinemia, anti-DNA and other ANAs, antiretroviral gp70 antibodies, circulating immune complexes, glomerulonephritis, and a low percentage of coronary arthritis. MRL/Mp-*lpr/lpr* mice also develop necrotizing polyarteritis and a rheumatoid arthritis (RA)-like disease accompanied by rheumatoid factors in serum. The NZB strain develops autoimmune hemolytic anemia.

Experiments addressing the genetics and the cellular or molecular mechanisms of SLE in these murine strains revealed that murine lupus is a polygenetic and multifactorial process, involving a combination of various genetically determined defects, which at least in part are different in each of the five models mentioned above. Studies of bone marrow irradiation chimeras indicate that murine lupus is caused by abnormalities at the hematopoietic stem cell level. The relative roles of T and B cells in the initiation and perpetuation of autoaggression are still a matter of debate. However, it appears clear that B cell hyperreactivity of lupus-prone mice is not due to defects intrinsic to immunoglobulin genes, but rather depends on T helper cells and/or polyclonal acti-

vation signals. Autoantibodies are of poly- or oligoclonal origin, the nephritogenic ones belonging to the IgG isotype and being cationic in charge. On the cellular level, dependent of the strain investigated and the age of donors, conflicting results have been obtained as far as the production of cytokines (e.g. IL-2), the response to them (e.g. IL-2 and IL-5), the cooperation between T and B cells, and the distribution of lymphocyte subsets are concerned. Both the *lpr* and the phenotypically similar, but non-allelic, *gld* (generalized lymphoproliferative disease) genes result in a massive accumulation of abnormal Thy-1⁺ CD5⁺ CD4⁻ CD8⁻ CD3⁺ TCR- $\alpha\beta$ ⁺ T cells, which anomalously express B cell markers (B220, PC1) and appear to be of polyclonal origin, the V β 8.2 and V β 8.3 T cell receptor genes being over-represented. Homozygosity in the recessive *lpr* or the *lpr^{cs}* mutations affects the expression (*lpr*) or signal-transducing capability (*lpr^{cs}*) of the CD95/Fas/Ap-1 surface receptor that initiates apoptosis-inducing pathways upon interactions with its ligand FasL, the molecule affected by the *gld* mutation. Since Fas is involved in the activation-induced cell death of T lymphocytes it is assumed that peripheral deletion is at least partially compromised in *lpr/lpr* and *gld/gld* mice. Moreover, it is known that Fas expressed on anergic B cells can receive apoptosis-inducing signals via interaction with FasL on T cells. Therefore, the *lpr* or *gld* mutation may compromise both T and B cell tolerance.

A dominant NZW locus contributing to severe SLE in (NZB $\times$ W)F1 maps within the H-2 region. This may be either due to the unique sequence of the NZW I-E β chain gene or to reduce production of the MHC class III product tumor necrosis factor (TNF). This latter finding could be pathogenetically relevant since treatment with TNF postpones the development of nephritis. Heterozygosity for the I-A β haplotypes of NZB and SWR has also been shown to correlate with the development of glomerulonephritis in crosses of the NZB strain with SWR mice. In other strains, no strong correlation with a particular H-2 haplotype was observed. Heterozygosity for the T cell receptor strongly correlates with nephritis in (NZB $\times$ SWR)F1 $\times$ NZB backcrosses, thus suggesting that the deletion of about half the T cell receptor V β genes which is found in healthy SWR parents might contribute to the development of SLE. In contrast, the NZW T cell receptor β chain locus, the C β 1, D β 1 and J β 1 regions of which have been deleted, probably does not contribute to the SLE of (NZB $\times$ W) hybrids.

In summary, the etiology of murine lupus appears to be rather complex and awaits further elucidation. Multiple loci accounting for different disease mani-

festations are currently under molecular study using a combination of classical genetic approaches (phenotyping of intercrosses or backcrosses) and microsatellite-based chromosomal maps. Interestingly, some of the loci determining lupus of (NZB $\times$ NZW)F1 mice map close to loci determining glomerulonephritis in MRL/*lpr* mice or diabetes in NOD mice, suggesting the existence of shared genetic mechanisms for some autoimmune disorders.

Conclusions

Animal models of spontaneous autoimmune disease have substantially contributed to our knowledge on the etiopathogenesis, genetics and molecular defects ultimately responsible for autoaggression. A variety of different mechanisms, including defects in the lymphoid lineages, endocrinological alterations, target organ defects, endogenous viruses or mutations in immunologically relevant molecules (e.g. MHC, T cell receptor genes), have been implicated in animal autoimmune disease and, in part, are also being described in human disease. Furthermore, the avant-garde position of animal models on the frontier of immunopathological research has allowed for the development of new therapeutic strategies for the treatment of autoaggression.

AUTOIMMUNE DISEASES

Ian R Mackay, Department of Biochemistry and Molecular Biology, Monash University, Melbourne, Australia

Autoimmunity and autoimmune disease

Autoimmune reactions to autologous molecules occur in health and may well be ubiquitous. Autoimmune disease is defined when such reactions become uncontrolled and result in structural or functional pathology. Normally there exists a physiological (natural) immunological tolerance to self constituents; previously, this was thought to be absolute, such that any immunological reactivity with autologous molecules would be abnormal. However, currently, tolerance can be expressed either as an *absolute absence*, or a *controlled level*, of autologous reactivity. Pathogenic autoimmunity might thus represent either an amplification of naturally occurring autologous reactivity, or be in some way qualitatively different.

Natural autoimmunity could serve physiological purposes: 1) early defense against infection with microorganisms that share cross-reactive epitopes with autologous molecules; 2) disposal of products of injury or tissue catabolism; or 3) facilitation of expansion in early life of immunological repertoires

through mutual stimulation of the antigen receptors on B cells due to anti-idiotypic connectivities. Natural autoimmunity includes both humoral (autoantibody) and cellular (T cell) activities. Natural autoantibodies are usually described as being of immunoglobulin M (IgM) isotype, broadly reactive, non-pathogenic and, to some degree, products of a particular lineage (B-1) of B cells characterized by the CD5 marker; in contrast, disease-related autoantibodies are class-switched to the IgG isotype, of focused reactivity, often pathogenic and are derived from somatically mutated Ig variable region (V) genes. However, some naturally occurring autoantibodies also exhibit these properties and, accordingly, would be difficult to distinguish from disease-related IgG autoantibodies in presymptomatic stages of autoimmune disease. Likewise, there are naturally occurring T lymphocytes reactive to various autoantigens, albeit at much lower numbers in blood than those observed in autoimmune disease. This is relevant to the diagnosis of autoimmune disease (see below), for which a major criterion is the coassociation of an 'appropriate' autoantibody; discriminative cut-off levels must optimally distinguish between

natural background reactivity and pathogenetically significant titers. Where T cell reactivity to autoantigen is applicable to the definition of an autoimmune disease, similar considerations will apply.

Designation of autoimmunity as a cause of a disease

Some authors, in discussing a particular disease, refer to it as 'an autoimmune disorder of unknown etiology'! Others even question whether autoimmunity is a legitimate etiology for any disease, perhaps forgetting Harrington's experiment in the 1950s wherein plasma transferred from a donor with 'idiopathic' thrombocytopenic purpura caused, in volunteer recipients, an immediate fall in blood platelet levels due to pathogenic anti-platelet autoantibodies. Witelsky in 1956 presented four 'postulates' to nominate a disease as autoimmune: 1) demonstration of free circulating antibodies that are active at room temperature, or of cell-bound antibodies detected using indirect means; 2) the recognition of the specific antigen against which these are directed; 3) the production of antibodies against the analogous antigen in actively immunized animals; and 4) pathological changes in the tissues of the actively sensitized animal resembling those of the corresponding human disease. However, the lack of models (components 3 and 4) precludes fulfillment of these postulates in many human autoimmune diseases.

Bayesian reasoning provides clinical and/or pathological features that can be factored in to presume an autoimmune basis for a given disease. These include: female gender; coassociation in the patient or family members of other diseases of autoimmune nature; histological evidence of 'organized' lymphoid infiltrates in the affected tissue including germinal centers, or deposition of immune complexes that contain autoantigen; association of the disease with particular alleles (usually class II) or the major histocompatibility complex (MHC), HLA in humans; and brisk responsiveness to corticosteroid drugs. As further evidence for an autoimmune basis for a given disease, there are models in animals, either spontaneous (lupus, hemolytic anemia or diabetes in particular strains of mice) or induced by immunization with the corresponding tissue in adjuvants (thyroiditis or encephalomyelitis in various species). Finally, in diseases designated as autoimmune, no other provocative causes should be demonstrable. Indeed, in chronic destructive diseases that *are* demonstrably due to a persisting microorganism, hallmarks of autoimmunity tend to be conspicuously absent, e.g. gastric mucosal destruction due to infection with *Helicobacter pylori* does not provoke the

parietal cell antibody response characteristic of autoimmune (pernicious anemia-type) gastritis. But there are exceptions, including spirochetal infection (cardiolipin antibody), hepatitis C virus infection (liver microsomal antibody, occasionally) and others.

In the absence of firm nominative criteria, a listing of likely autoimmune diseases is necessarily provisional (Table 1). A somewhat imperfect classification is as follows:

1. Organ and autoantibody specific, i.e. diseases in the 'thyrogastric cluster'.
2. Tissue and autoantibody specific, i.e. diseases in which a 'disease-relevant' target autoantigen exists, but this is widely 'dispersed' throughout the body e.g. hemolytic anemia (erythrocytes), myasthenia gravis (acetylcholine receptor).
3. Diseases that are organ or tissue specific, and in which there is a disease-specific autoantigen(s), but this is distributed in all cells and thus not 'disease relevant', e.g. primary biliary cirrhosis and mitochondrial autoantigens, or Sjögren's syndrome and ribonucleoprotein autoantigens.

Table 1 A partial list of autoimmune diseases

Hashimoto's thyroiditis
Primary myxedema
Graves' disease
Pernicious anemia
Autoimmune atrophic gastritis, pernicious anemia
Addison's disease
Ovarian failure, premature menopause
Insulin-dependent diabetes mellitus
Goodpasture's syndrome
Myasthenia gravis, Lambert-Eaton syndrome
Male infertility (few cases)
Pemphigus, bullous pemphigoid
Psoriasis (possibly)
Crohn's disease (possibly)
Sympathetic ophthalmia
Autoimmune uveitis
Multiple sclerosis
Autoimmune hemolytic anemia
Autoimmune thrombocytopenic purpura
Autoimmune neutropenia
Primary biliary cirrhosis
Chronic active hepatitis, 'cryptogenic' cirrhosis
Ulcerative colitis (possibly)
Sjögren's syndrome
Rheumatoid arthritis
Dermatomyositis
Polymyositis
Scleroderma
Anti-phospholipid syndrome
Mixed connective tissue disease
Vasculitis
Vitiligo
Systemic lupus erythematosus

4. Diseases that are multisystem and 'nonfocused', with autoimmune reactivity against antigens associated with various non-tissue-specific intracellular organelles, e.g. systemic lupus erythematosus (SLE).

Etiology and pathogenesis

Germline genetic influences

An important genetic component in autoimmune disease is female gender, with the female:male ratio ranging up to tenfold, although a notable exception is insulin-dependent diabetes mellitus (IDDM) that occurs at prepubertal ages with an equal gender incidence. The influence of female sex hormones on immune responsiveness, and perhaps an immunopotentiating gene on the X chromosome, explains the female predisposition to autoimmunity. A strong genetic predisposition to autoimmunity is conferred by alleles of the MHC, in humans and in experimental models, particularly at the class II loci, HLA-DR, -DQ, -DP rather than the class I loci, HLA-A or -B. Class II alleles encode heterodimers that present antigenic epitopes to T cell receptors, and such MHC molecules may contain, in their hyper-variable regions, a sequence of amino acids that represents the disease susceptibility motif (DSM); this explains for example the HLA associations, DR1, DR4, with rheumatoid arthritis. The DSM may confer a high binding affinity for an autoepitope that can engage the T cell receptor, or may act to bias the thymic selection of the T cell repertoire.

Studies on genetic linkages in families with multiple members with an autoimmune disease e.g. IDDM, or in animals using backcrossing and chromosomal localization, e.g. lupus mice, indicate the existence of many other gene loci, encoding either 'immunologically relevant' genes or 'non-immunologic' (background) genes, that confer or alleviate risk for autoimmunity. Examples would be genes that govern expression of cytokines, chemokines or adhesion molecules, or genes that influence expression of molecules that promote or inhibit apoptosis, *fas* and *bcl*. Still further genetic effects on autoimmunity could relate to the antigenic composition of the target organ itself, or to autoantigenic molecules as products of alternatively spliced genes, isoforms of enzymes, or to other structural or functional polymorphisms of potential autoantigens.

Somatic genetic influences

Susceptibility to autoimmune disease may depend on somatic genetic effects (mutations) in postnatal life. The best example is antigenic stimulation of B lymphocytes in germinal centers of lymph nodes, with

ensuring hypermutation of antibody V region genes to generate affinity maturation of antibodies. Thus B lymphocytes with reactivity with autoantigens may emerge as a 'byproduct' of affinity maturation of antibodies to bacterial antigens, and may persist if tolerogenic processes fail, with ensuing 'rescue' of such autoimmune B cells from apoptosis. Various other somatic genetic mutations in postnatal life could predispose to autoimmunity, e.g. those that influence patterns of cytokine secretion, or processes of apoptosis.

Environment

The environment can interact with genetic predisposition to induce autoimmune disease. Viewed most simply, any cause of tissue damage can result in release of cellular products which, if exposed to antigen-presenting cells of individuals with 'susceptibility genotypes', in an appropriate microenvironment such as cytokine excess, could stimulate self-reactive T cells that normally circulate at low levels. In the case of infectious damage, there is the added possibility of antigenic (or epitope) mimicry. This idea is based on molecular homologies between a constituent protein antigen of a microorganism and host being sufficiently close that the 'protective' response to the organism becomes cross-reactive with 'self'. An example of a break in tolerance initiated by molecular mimicry is the provocation by streptococcal cell wall antigens of rheumatic endomyocarditis. Currently, molecular biological techniques for identifying sequences of autoantigenic epitopes have been combined with searches of gene and protein databanks to reveal potentially informative homologies; however, such comparisons often fail to acknowledge that B cell epitopes, including autoepitopes, are usually conformational rather than linear. Thus molecular mimicry may be more applicable to short linear T cell epitopes.

Other relevant environmental influences are ultraviolet radiation, chemicals including mercuric chloride that induce autoimmunity in rodent models, and medicinal drugs that induce various autoimmune syndromes including SLE, hepatitis and myasthenia gravis. Good explanations for the induction of autoimmunity by these influences are lacking; sunlight might act to create neoepitopes in skin cells, mercuric chloride may cause structural alterations in MHC molecules on antigen-presenting cells, and medicinal drugs may yield molecules that generate compound epitopes with cellular constituents.

Induction of autoimmune disease

The critical elements for the induction of autoimmune responses are: 1) the autoantigenic epitope;

2) processes that facilitate the presentation of the autoantigenic epitope to the immune system; and 3) recognition of the epitope by T and B lymphocytes that have evaded tolerogenic influences.

To serve as an autoantigen, a self molecule should activate both T and B lymphocytes. Autologous molecules will not be recognized as autoantigens if deletional processes have completely removed any cognate responsive T cells in the thymus, or B cells in the bone marrow. T cells can escape deletional tolerogenesis in the fetal thymus if the requisite self molecule is either not represented there, or is not adequately processed by antigen-presenting cells, or if its affinity for the antigen receptor on intrathymic T cells is too low. Thus some self-reactive T cells do exit from the thymus to the periphery: however, these are not necessarily dangerous as they may have only a low affinity for autoantigens and are not readily activated; or, being of a naive phenotype, will not express the surface adhesion molecules required for their transit into tissue parenchyma.

Autoreactive B cells can arise in two sites, the bone marrow during lymphogenesis, or lymph node germinal centers by affinity maturation during responses to extrinsic antigens (see above). B cells at both sites are subject to various tolerogenic influences, including antigen in excess, which induces cell death by apoptosis. Again, however, there is 'leakage' in health of self-reactive B cells from these sites into the periphery; evidence for this is the presence in the circulation, particularly in aging, of various autoantibodies, and also B cells capable of binding labeled autoantigens. A low degree of B cell autoimmunity may well be 'innocuous', if not beneficial (see above), provided that there is no source of potent contiguous T cell help.

Effector activities in autoimmunity

Effector activities depend on the various functions of B or T lymphocytes or, probably, both sets of cells, in unison. B cells and circulating autoantibody are the clear cause of autoimmune pathology in hemolytic diseases, or SLE in which damage results from deposition of immune complexes, or diseases in which autoantibody binds to cell surface receptors, either to inhibit a neurotransmitter, e.g. acetylcholine receptor in myasthenia gravis, or to stimulate a hormone receptor, e.g. the thyrotropin receptor in Graves' disease. Another role for B cells is to act as antigen-presenting cells, in a focused way, as autoantigen can be specifically captured by the B cell immunoglobulin receptor for presentation to autoimmune T cells, thus sustaining the autoimmune reaction. CD4⁺ helper T cells are the likely effectors of damage in autoimmune disease of parenchymal

tissues, thyroid gland, stomach, brain, synovium, pancreatic islets, etc., presumably by release of injurious cytokines, particularly tumor necrosis factor (TNF), or injurious enzymes (granzymes). CD8⁺ cytotoxic T lymphocytes (CTLs) are less easily studied functionally as effectors of autoimmune damage and data are scarce. As judged by the infrequency of MHC class I associations with autoimmune disease, CD8⁺ CTL-mediated damage might be relatively less important in autoimmunity. However, immunohistochemical studies of tissue lesions often show a striking infiltration of CD8⁺ T cells in contiguity with damaged cells and, in animal models, cell transfer studies have implicated CD8⁺ CTLs as early effectors, e.g. in autoimmune islet cell damage in nonobese diabetic (NOD) mice.

Regulation of autoimmunity

Self tolerance and avoidance of autoimmunity are of such fundamental importance to the organism that several 'layers' of tolerogenesis are in place. The first and fundamental layer, 'central' tolerance, is deletion of lymphocytes in the primary lymphoid organs, thymus or bone marrow, consequent on high-affinity contact between autoantigen as ligand and antigen receptors on nascent T or B cells, i.e. negative selection. Deletional self tolerance has been elucidated by recent studies on transgenic mice in which cDNA for a marker antigen, e.g. hen-egg lysozyme, is introduced in embryonic life, and hence is treated as self; in 'double' transgenic mice there are additionally introduced genes that encode T cell or B cell antigen receptors for the transgenic molecule.

Processes of 'peripheral' tolerance operate to limit the activity of autoreactive cells that have escaped deletion in the thymus or bone marrow. Thus 1) thymic emigrant T cells have a 'naive' phenotype and lack activation molecules needed for extravasation through vascular endothelium into tissue parenchyma; 2) T cells that encounter autoantigens in the blood or on the surface of tissue cells do not receive a critical 'second signal' that is provided only by 'professional' antigen-presenting cells, and respond by anergy rather than activation; 3) particular cytokines may deflect a damaging autoreactive CD4⁺ T helper cell response from the T_H1 inflammatory type to the more benign T_H2 antibody dominated type; 4) autoimmune B cells remain innocuous if they fail to obtain adequate helper signals from T cells that may be adequately tolerized; and, finally, 5) there are mechanisms of 'dominant' tolerogenesis, also called suppression, which can prevent autoimmunity or even override established self-reactive effector processes. Autoimmunity in states of natural and experimentally induced T cell lymphopenia is evidence for

the existence of a regulatory/suppressive subset of T lymphocytes. Dominant tolerogenesis may also be mediated by anti-idiotypic antibodies; such antibodies are directed against the combining site of the antibody molecule itself. Anti-idiotypic antibodies to autoantibody molecules appear to exist in normal sera, and are considered to explain the beneficial therapeutic effect in certain autoimmune diseases of pooled normal human immunoglobulins given intravenously.

Diagnosis

Autoimmune diseases are usually diagnosed according to the functional deficits that ensue in affected organs, rather than by their immunological features *per se*. This applies to autoimmune disease affecting the thyroid gland, adrenal gland, pancreatic islets, stomach, liver, kidney, muscles, neural transmitters, etc. However, testing for the disease-relevant autoantibody will in many instances provide specific and decisive diagnostic information, exemplified by testing for the antiglobulin reaction in hemolytic anemia, and for autoantibodies to acetylcholine receptor in myasthenia gravis, adrenal cortical cells in Addison's disease, dsDNA in SLE, mitochondrial pyruvate dehydrogenase enzyme complexes in primary biliary cirrhosis, or to the combination of nuclei and F actin in type 1 autoimmune hepatitis. An interesting application of modern sensitive and automated tests for autoantibodies, utilizing recombinant autoantigens, is screening for presymptomatic autoimmune disease, e.g. assays for anti-GAD (glutamic acid decarboxylase) and other islet autoantigens to detect presymptomatic IDDM among first-degree relatives, or even among populations.

Treatment

Many of the organ-specific autoimmune diseases are adequately treated by replacement therapy when terminal destruction ensues, e.g. thyroiditis, adrenalitis, gastritis, insulinitis, etc.; however, the state of autoimmunity must be 'controlled' when disease affects vital organs or tissues, such as the liver in autoimmune hepatitis or muscles in autoimmune polymyositis, or when the disease is systemic and many tissues are at risk, as in SLE.

Traditionally, 'control' over the immunologic activity in autoimmune disease has been with corticosteroid drugs, which have particular efficacy in blocking unwanted effects of antigen-antibody reactions. The action of corticosteroids can be supplemented by 'immunosuppressive' drugs of the types used to prevent rejection of transplanted allografts: azathioprine, cyclophosphamide and cyclo-

sporine; however, because prolonged usage of these drugs can have various adverse effects, therapists are seeking more subtle immunological interventions. These include blockage by monoclonal antibodies of critical components of the immune response, and particularly the receptor complex of CD4 T cells, T cell cytokines including TNF α , or B cell/antibody receptors by infusion of normal polyclonal human IgG that is presumed to contain anti-idiotypes to autoantibody molecules. There is theoretical, and some practical, promise in 'at source' therapy which is to re-establish broken tolerance to culprit autoantigens. This depends on the autoantigen being administered as preparations and by routes that are more conducive to tolerance than to immunity – the 'negative vaccine' idea. Delivery of the autoantigen via the intestine, 'oral tolerance', is currently favored. The obvious benefits of this approach for the prevention of autoimmune disease should justify the years of developmental study that seem needed to bring it into routine use.

AUTOIMMUNITY

Peter J Delves, Department of Immunology, University College London Medical School, London, UK

At the beginning of this century Paul Ehrlich used the expression 'horror autotoxicus' to describe the body's apparent inability to respond to self antigen and he suggested that nonreactivity may be mediated by the lymphoid system. Evidence that these control mechanisms can sometimes fail was provided afterward by the observation of Donath and Landsteiner that patients with paroxysmal cold hemoglobulinemia possess antibodies against their own erythrocytes.

The experiments of Rivers, Sprunt and Berry in the early 1930s showing that injection of monkey brain antigens back into monkeys provoked encephalomyelitis provided the first experimental model of autoimmune disease. A decade later, Owen's observation that dizygotic cattle twins sharing the same blood supply during embryonic life did not destroy each other's nonidentical erythrocytes (even if these were injected in adult life) suggested that self tolerance is acquired during ontogeny. Such chimeric cattle are able to exchange skin grafts without subsequent tissue rejection. In 1953 Billingham, Brent and Medawar demonstrated that neonatal injection of cells from CBA strain mice into A strain mice allowed the mice to later accept CBA skin grafts. Three years after these experiments, a series of classical papers on thyroid autoimmunity were to firmly establish the role of autoimmune phenomena in producing disease. Rose and Witebsky induced both autoantibodies and thyroiditis by immunizing rabbits with thyroid extract in Freund's adjuvant; Roitt, Doniach and Campbell demonstrated autoantibodies to thyroglobulin in Hashimoto's disease; and Adams and Purves discovered stimulatory autoantibodies directed against the thyroid-stimulating hormone (TSH) receptor.

Consequences of autoimmunity

Autoimmunity is defined as an immune response leading to reaction with self antigen, i.e. any molecule that is a normal body constituent of the animal mounting the response. Self reactivity can arise either

through the triggering of receptors directly by autoantigen or by virtue of cross-reaction between foreign and self antigens. Topographic similarity of B cell epitopes or sequence homologies of linear T cell epitopes may lead to such cross-reactions and it is highly unlikely that the immune system is able to recognize all foreign antigens specifically without some recognition of self epitopes also occurring.

Techniques such as polyclonal activation of cells with mitogens, and the establishment of lymphocyte clones and hybridomas, have established that self reactive T and B lymphocytes are frequently found in individuals who lack readily detectable autoantibodies in their serum. Indeed, at least some degree of self reactivity appears to be a normal physiological phenomenon during lymphocyte development and perhaps may be necessary in preparing the immune system for its future encounters with foreign antigen. The B-1a (CD5⁺, Mac-1⁺, CD23⁻, strongly sIgM⁺) subset of B lymphocytes are found mainly in the peritoneal cavity where they are self-renewing and express germ line V genes encoding polyspecific low affinity IgM autoantibodies bearing cross-reactive idiotypes. This B cell subset is elevated in, for example, the autoimmune NZB mouse and in patients with rheumatoid arthritis. Low affinity IgM autoantibodies are probably not pathogenic. Encounter with nonidentical cross-reacting foreign antigen will, in the presence of T cell help, lead to affinity maturation within germinal centers, thereby generating antibodies with high affinity for foreign antigen which simultaneously lose their original self-reactivity. However, as certain self antigens such as idiotypes form key recognition structures for immunological regulation it is crucial that the immune system retains the ability to recognize these particular self components.

The pathogenicity of an autoimmune response is determined not only by the magnitude but also by the nature of the response. For instance, although 10–20% of clinically normal individuals possess low titers of autoantibodies specific for thyroglobulin,

and although these antibodies are present at higher titers in about 70% of Hashimoto's disease patients, it is autoantibodies to another thyroid component, thyroid peroxidase, which show a stronger correlation with histopathological lesions. These autoantibodies occur in 95% of patients with Hashimoto's disease and, unlike most thyroglobulin autoantibodies, are complement fixing and therefore potentially cytotoxic to thyroid epithelial cells. Another example underlining the distinction between autoimmunity and disease is seen in patients treated for longer than 1 year with the drug procainamide (used to control cardiac arrhythmia). Over 90% of these patients develop IgM antibodies reactive with a broad spectrum of self histones but it is only in the 10–20% of patients who develop high levels of IgG antibodies specific for the H2A-H2B histone dimer bound to DNA that a lupus-like autoimmune disease arises. In the case of immunoglobulin, different parts of the same molecule can elicit both physiological (idiotypic) and potentially pathogenic (rheumatoid factor) autoantibodies.

Animal models have confirmed the importance of cell-mediated immune responses in the development of autoimmune disease; the adoptive transfer of autoantigen-specific T cell clones is often sufficient to induce disease in normal recipients. Most autoimmune diseases probably have both T and B cell components and in some situations other mechanisms involving natural killer (NK) cells or antibody-dependent cellular cytotoxicity may play a role in the pathogenic process.

Mechanisms controlling autoimmunity

Because pathogenic autoimmunity is the exception rather than the rule, mechanisms must exist which normally prevent the development of autoimmune disease. In this respect the immune system is able to distinguish self from nonself and, ultimately, becomes 'tolerant' towards most self antigens. However, as alluded to above, many of the tolerance mechanisms controlling autoimmunity may be less concerned with repression of all self reactive lymphocytes than with preventing the development of pathogenic T cells and autoantibodies. Indeed, there is evidence from studies in transgenic mice to suggest that, in situations in which high-affinity antiself B cells are anergized, low-affinity antiself B cells escape this tolerization process.

The danger model of immune responses proposes that, rather than discriminating self from nonself, the immune system primarily distinguishes between harmless and harmful. In this scenario, self would normally be considered harmless and would fail to

trigger a response. However, a response to harmful situations would occur due to upregulation of costimulatory molecules on antigen-presenting dendritic cells following signals induced by microbial antigens, cell stress or necrotic cell death.

Although evidence for several different tolerance mechanisms exists, the relative role of each of these in controlling autoimmunity remains to be firmly established. For a long time it was thought that many self antigens were sequestered in 'privileged sites' and therefore shielded from the immune system. The advent of sensitive assay techniques allowed the detection of, for example, low levels of circulating thyroglobulin (an autoantigen previously thought to be completely sequestered within the thyroid). Nevertheless, it is believed that for a few self molecules, such as lens proteins, sperm and brain antigens, this concept largely holds true.

The 'forbidden clone' theory put forward by Burnet in the 1950s suggested that deletion of self reactive clones led to self tolerance. Although it is now clear that this is not a universal mechanism for avoiding autoimmunity, clonal deletion is known to occur for some self antigens. Mice bearing, for example, particular Mls antigens eliminate any T cells which are expressing T cell receptor β chain variable region genes associated with recognition of these antigens. In situations where self reactive cells are not deleted they either become anergic or are actively suppressed by regulatory mechanisms which have evolved in order to restrain harmful autoimmunity. T cell-mediated suppression maintains control over both B lymphocyte and effector T lymphocyte responses, so that any defect in antigen-specific or idiotype-specific suppression might allow autoimmune responses to occur. Conversely, increases in helper T cell activity may allow normally quiescent self reactive lymphocytes to mount an autoimmune attack. In instances in which potentially autoreactive B lymphocytes normally remain inactive due to tolerance of the relative helper T cells, the provision of new carrier determinants can provide a 'bypass' mechanism allowing T cell help for autoantibody production. It has been shown that tolerance can be broken experimentally using chemically modified or hapten-conjugated protein antigens and it has been suggested, for example, that the Coombs' positivity of some patients treated with methyl dopa may be due to the drug complexing with erythrocyte antigens, thereby providing carrier determinants which will stimulate cognate T cell help. In other cases, T cell epitopes on the autoantigen may not be effectively presented during tolerance induction in the thymus and so potentially autoreactive T cell clones escape deletion. Only if higher levels of these

normally 'cryptic' epitopes later become effectively presented in the periphery, due perhaps to altered processing or presentation of the self antigen, will autoimmune reactivity manifest itself. Furthermore, once initiated, the autoimmune response may spread to other epitopes on the same or different antigens, a process that could be fueled by the local production of inflammatory cytokines which might further lead to upregulation of cell surface molecules involved in antigen presentation and cellular activation.

Idiotypic networks may be important in the control of immune responses to autoantigen; defects in this regulatory network could provide a pathway by which self reactivity can arise. For example, anti-idiotypes to DNA-specific autoantibodies have been described in the sera of patients with inactive systemic lupus erythematosus (SLE) which were absent in those with active disease, suggesting that the presence of these antibodies may influence the course of the disease. In the anti-insulin response seen in patients with insulin-dependent diabetes mellitus (IDDM), idiotypic determinants have been reported to be cyclically expressed even though the total amount of anti-insulin remained constant, again suggesting that idiotypic interactions are involved in regulating this response. In some instances pathogenic autoantibodies may be internal image anti-idiotypes which are directed against antiviral antibody and bind to the same cell surface molecule that is used as a receptor by the virus.

Major histocompatibility complex (MHC) class II gene products are normally expressed only on 'professional' antigen-presenting cells (APCs) but they are sometimes also aberrantly expressed on a variety of cell types during autoimmune disease. It has been shown that such cells themselves are then also able to present antigen. Aberrant expression of MHC class II may be the result of cytokine secretion by cells already involved in an ongoing inflammatory response, and might provide a mechanism for perpetuation of the disease.

Regardless of the cell type expressing MHC class II it is known that autoimmune disease is influenced by MHC (particularly class II) haplotype. As the majority of autoantigens are likely to be T dependent, the ability of self peptides to associate with self-MHC at a concentration necessary for T cell activation will be central to the induction of an immune response.

Individuals bearing HLA-DR4 are nearly six times more likely to develop rheumatoid arthritis (RA) than those lacking this haplotype. For some autoimmune diseases there appears to be a synergistic effect between MHC genes; individuals who bear HLA-DR3 or HLA-DR4 have an increased risk (of

between 2 and 7) of developing IDDM but for someone bearing both these haplotypes the relative risk increases to 14. In IDDM the particular residue at position 57 of the DQ β chain appears, in concert with other residues, to be important in determining disease susceptibility in some caucasian populations.

Molecular mimicry of self antigen by invading organisms can lead to a breakdown of self tolerance as seen in the cross-reactions between streptococcal M protein and cardiac myosin in rheumatic fever and between both brain and heart tissue and *Trypanosoma cruzi* in Chagas disease. Many other examples of autoantibodies cross-reacting with pathogens have been described. Cross-reactivity between self and foreign antigens is also seen for T lymphocytes as demonstrated by the existence of T cell clones specific for determinants on a mycobacterial hsp65 and a human hsp60 which share 48% amino acid sequence homology. Polyclonal lymphocyte activation occurs in response to some infections, for example with Epstein-Barr virus, and has been proposed as a possible mechanism involved in the development of autoimmunity. However, although some of the clones activated may be specific for self antigen these will usually be short lived and produce IgM antibodies of low affinity. Experiments involving neonatal thyroidectomy of autoimmune obese strain chickens demonstrated that the presence of autoantigen is required for the development of thyroglobulin autoantibodies and therefore in this instance these antibodies are not induced by nonspecific activation of B cells.

Somatic mutation of antibody variable region genes is a further mechanism by which autoantibodies may arise. It is known that a single, naturally occurring, point mutation can change an antibody with specificity for phosphorylcholine into an antibody that recognizes double-stranded DNA, protamine and cardiolipin. This antibody has therefore lost the ability to bind to bacterial antigen but acquired binding for self antigen. Despite the fact that autoantibodies are normally restricted in their epitopic specificity (for example to two or three paired determinants on human thyroglobulin) they are usually polyclonal. It is therefore unlikely that somatic mutation on its own provides an explanation for autoimmune disease, although triggering of idio-type-specific T helper cells might allow a single clone to initiate a polyclonal response via network interactions. It is generally accepted that the development of most autoimmune disease is multifactorial in nature. Some of the animal models suggest a role for ADCC or NK cells. Other factors that may influence the initiation and development of the disease are defects in immune regulation (for example T_H1/T_H2

Figure 1 The multifactorial nature of autoimmunity. ●, Autoantigen; APC, antigen-presenting cell ('professional' or aberrant class II expression); Th, helper T cell (antigen- or idiotypic-specific, carrier-specific for T cell bypass); Te, effector T cell (for example cytotoxic T cell); Ts, suppressor T cell; B_{id}, autoantibody-secreting Id⁺ B cell; B_{aid}, anti-idiotypic B cell.

imbalance) and in the target antigen, sex hormones (autoimmunity is more common in females than in males), diet, and the time and nature of exposure to infectious agents. Some of the above concepts are drawn together in Figure 1.

Intervention in autoimmunity

As a clearer picture emerges of the precise mechanisms involved in the breakdown of self tolerance, therapeutic approaches for the autoimmune diseases can begin to address the underlying defect, i.e. the specific autoimmunity. At present, when endocrine tissues are destroyed, as in Hashimoto's disease or IDDM, hormone replacement therapy is utilized. Antithyroid drugs, thyroidectomy and radioactive ablation are used in Graves disease rather than elimination of the TSH receptor autoantibody response. The immunosuppressive regimens used for systemic autoimmune conditions such as SLE and rheumatoid arthritis are crude attempts to dampen the whole

immune system rather than control the specific autoimmune response. More rational approaches to therapy are now beginning to emerge based upon, for example, oral or nasal tolerance induction, the use of cytokine antagonists, and intervention using peptide-based therapeutics to directly block T cell activation.

AUTORADIOGRAPHY

Manoj Raje and Gyan C Mishra, Institute of Microbial Technology, Chandigarh, and National Centre for Cell Sciences, Pune, India

Autoradiography is a method of localizing radioactive atoms in a specimen. The method briefly comprises of:

1. *Labeling* of a suitable molecule with a radio-nuclide, serving as a tracer.
2. *Incorporation* of the radioactive tracer into the sample under study.
3. *Processing* of the sample by some suitable means.
4. *Exposure* by placing the prepared sample in close approximation with a special photographic emulsion so that the products of radioactive decay in the sample may interact with the silver halide crystals of the emulsion to form latent images.
5. *Developing* the latent images to convert them into silver grains.
6. *Fixing* the resultant autoradiogram by washing away unreacted silver halide crystals.

The silver grains thus deposited are visualized and their position noted in relation to the underlying sample structure to try and understand the distribution of the label in the sample. Depending upon the nature of the information sought, autoradiography can be carried out at three levels:

1. *Gross level*: in the case of samples such as entire organs, large tissue slices, leaves, gels, etc., where the resolution required is of the order perceived by the naked eye (0.2 mm)
2. *Microscopic level*: cellular and tissue level localization, resolution of around 1–5 μm required.
3. *Ultrastructural level*: subcellular detection and localization with a resolution in the submicron range.

Further discussion will be confined to autoradiography of the microscopic and ultrastructural levels only.

For the successful application of the autoradiographic technique to accurately localize and quantify

a biological molecule of interest it is necessary to have detailed information of the biochemical, physiological and pharmacological processes involved in its uptake, distribution and clearance. Also important is the need to have knowledge of the efficiency and resolution obtainable by the experimental technique. Efficiency is defined as the number of silver grains formed per radioactive disintegration in the sample. It depends upon:

- Dose, nature and energy of the radioactive emission.
- Thickness of the sample and emulsion.
- Developing parameters.

The resolution obtainable can be considered in three ways:

- Distance of separation between the points of radioactive decay and grain formed.
- Ability to separate two points of radioactive decay.
- Ability to separate the individual grains formed.

Resolution is also modulated by the nature and energy of the radioactive emission and developing parameters; it also depends upon the size of silver halide crystals in the photographic emulsion.

Commonly used radioisotopes in biological studies

Not every radioisotope will be suitable for a particular autoradiography procedure. The criteria for determining suitability are:

1. *Nature of emission*. Particle emitters are preferred. Gamma and X-ray emitters have very poor efficiency. Electron emitters are usually the most favorable.
2. *Particle energy*. Generally the higher the energy the lower is the efficiency of detection. This is because high-energy particles have a tendency to

escape from the sample and emulsion. β Particles with energies above 0.5 MeV are usually very difficult to detect. A 'high' energy will also mean that the particle will travel further before forming a latent image, hence resolution will also be poor.

3. **Half-life.** If the half-life of the radioisotope used is too short (less than 30 days), most of the radioactivity will disappear during sample processing. On the other hand, use of isotopes with very long half-lives will mean a very low specific activity (few radioactive decay events per unit time) and hence the exposure time would have to be lengthened unduly to collect the requisite number of latent images in the emulsion.

Some of the commonly used radioisotopes in biology are listed in Table 1. The exact choice of a particular radionuclide is dependent upon its biological relevance. The final decision in determining a suitable isotope should be made keeping in mind the nature of the biological process under study. The radio-labeled biomolecule prepared has to be purified, checked for specific radioactivity and assayed for biological activity before use for autoradiography.

Dose and administration of radiochemicals

The dose of radioactivity to be administered depends upon the detection system and resolution sought. High-resolution autoradiography is usually carried out with thin films/sections of the sample where the mass of the tissue present is very small. It is therefore necessary to use a high radioisotope concentration and extended exposure time. Although methods are available for the estimation of exposure time for a given level of radioactivity in a sample block, it is usually the practice to prepare autoradiographs in batches. Administration of the radiomolecules can be by one of several routes. In the case of animals, oral intake, direct infusion into arteries/veins or ventricular spaces, injection into peritoneum, etc., can all be considered. For labeling cell suspensions, *in vitro* incubation in culture medium is by far the most rapid, efficient and inexpensive method.

Table 1 Radioisotopes used in biology

Isotope	Nature of emission	Energy (MeV)	Half-life
^3H	β	Low: 0.018	Long: 12.26 years
^{14}C	β	Medium: 0.159	Very long: 5760 years
^{35}S	β	Medium: 0.167	Moderate: 87.2 days
^{32}P	β	High: 1.71	Short: 14.3 days
^{125}I	Auger electron from electron capture reaction	Low: 0.008	Moderate: 60 days

Emulsions used

Photographic emulsions used for high-resolution autoradiography are characterized by a small size of silver halide crystal. The larger the crystal diameter, the poorer is the resolution obtainable; however, greater efficiency is obtainable with larger crystals. Apart from small size, for high resolution work in an electron microscope the emulsion of crystals has to be applied in a monolayer over the sample. There are several suppliers of autoradiography emulsions (Kodak, Sakura, Ilford) with various crystal diameters available.

Application of emulsion to radiolabeled samples

Once a sample has been prepared for autoradiography it is brought into intimate contact with the emulsion. There are primarily two methods for forming a monolayer of emulsion on the sample.

Loop method

A drop of liquefied emulsion in the form of a bubble in a wire loop is applied on to the surface of a sample. This method is commonly used in ultrastructural analysis. The sample is in the form of ultrathin sections/film mounted on a grid.

Flat substrate method

Frequently used in light microscopic studies, here samples mounted on glass slides are dipped into a beaker of liquefied emulsion to form a uniform coat of silver halide crystals. A variation of this method involves first casting of the emulsion films on glass slides, from where they are floated on water and allowed to settle on to the sample.

Exposure

Exposure of emulsion-coated samples is carried out in dessicated light tight boxes at 4°C. The emulsions must be shielded from stray light and radiation. Low temperature and humidity is important to prevent

the fading of latent images (resulting in lowered efficiency). The time of exposure can vary from a few weeks to a year and depends upon the nature of the experiment and the radioisotope used. In our laboratories we usually check batches of samples after every few weeks of exposure.

Development

Development involves precipitation of silver atoms at the site of the latent image to form silver grains, which are visualized in a microscope. A generalized method of development involves immersion of the emulsion coated sample in a suitable fine grain developer (for example Kodak D-19 or Microdol X) for a standardized period of time (usually for a few minutes). After rinsing in distilled water the emulsion is fixed in sodium thiosulfate solution for at least 20 minutes and then washed extensively in distilled water. Care has to be taken to ensure that at no point is the surface of the sample contaminated with any precipitate or other material. After washing, the sample can be stained before examination under the light or electron microscope. It should be noted that different developers yield different numbers of grains (different sensitivity); moreover, the shape of the silver grains deposited also varies with developer, a factor which affects the resolution.

Control observations

The successful validation of any autoradiographic experiment requires a proper set of control observations for determination of background and presence of chemography.

Background

Silver grains deposited due to radioactivity of the tracer molecules incorporated into the sample constitute the signal. However, some additional grains can also develop for nonspecific reasons. These constitute the noise or background of the system. Generally the background should not exceed more than 5% of the signal grain density. Background can be estimated by taking the ratio of the grains present over the target tissue to the grains present over the same area of empty section (only embedding material coated with emulsion). The factors contributing to background are:

- Exposure to stray light or radiation.
- Pressure during drying of emulsion film.
- Static discharges in the vicinity (common in low-humidity workplaces).
- Overdevelopment (excessive time and/or temperature).

Chemography

Induction of grain formation by the chemical action of sample components on silver halide crystals is known to occur and is called positive chemography. The reverse process, of eradication of latent images by chemicals in the sample, is known as negative chemography. The former causes an increase in the background, while the latter lowers the efficiency. Interposing a thin inert layer of carbon between the sample and the emulsion usually minimizes the problem. A control for positive chemography is a non-radioactively-labeled, identically-treated sample. For negative chemography a control would be a light-fogged, identically-treated sample.

Interpretation of results

The simplest method is to assume that the grain observed overlies the point of radioactive decay and hence represents the site of the target molecule. For lower resolution studies at the light microscopic level this assumption may work; however, in the case of electron microscopy autoradiography this assump-

tion need not hold true and careful analysis of the images obtained has to be made. There are two methods in common use for localization of the radioactive decay event in a sample with relation to the observed grain density. These are known as the probability circle analysis and the cross-fire method (see Williams (1985) for detailed methodology).

Some areas of application

Autoradiographic techniques have been used extensively to study the binding of a variety of small molecules such as peptides, drugs and hormones to a variety of target sites in cells and tissues. The number

of conserved subunits in chromosomes was demonstrated using autoradiography. Many important observations have been made on macromolecular metabolism, synthesis and secretion using these techniques. The method has also been successfully applied to the study of virus particles and nucleic acids. In our laboratories we have used autoradiography and electron microscopy to demonstrate the binding of a costimulatory protein to its receptor on the surface of CD4⁺ T lymphocytes (Figures 1 and 2).

AVIAN IMMUNE SYSTEM

J Richard L Pink, Pharma Research PRPN, F Hoffmann-La Roche Ltd, Basel, Switzerland

Olli Vainio, Department of Medical Microbiology, University of Turku, Turku, Finland

The species studied by avian immunologists include turkeys, ducks, pigeons and Japanese quail. However, the contributions of the domestic chicken (*Gallus gallus*) to immunology far outweigh those of other birds, and indeed exceed those of other species except humans and mice. The contributions date back to 1880 (Pasteur's key observation of fowl cholera attenuation, on which much vaccine development is based), and are continuing at present with the para-aortic localization of hematopoietic precursors in very early embryos. Some important immunological results obtained using chickens or chick embryos are the discoveries of tumor viruses (including endogenous viruses) and interferon; the association of the major histocompatibility complex (MHC) with resistance to viral disease; induction of tolerance by embryonic parabiosis; the definition of separate B and T lymphocyte lineages following Glick's elucidation of the role of the bursa; quantitation of graft-versus-host reactions and frequencies of alloreactive T cells; and evidence that the primary lymphoid organs are colonized by bloodborne hematopoietic stem cells, that a gene conversion-type mechanism can play a major role in the development of antibody variability, and that immunoglobulin G (IgG)- and IgA-producing cells are derived from IgM-positive precursors.

Avian and mammalian immune systems have much in common. However, there are important differences, emphasized in this entry, between them, notably in the structure of lymphoid organs, the ways in which antibody variability is generated, and the arrangements of Ig and MHC genes. The main advantages of chickens in immunological experiments are the accessibility of the embryo, the ease of manipulating B cell development in the bursa, and the ready availability of peripheral blood and lymphoid organs from birds with defined genetic background. Young chicks are easy to immunize, bleed and operate, and can be kept in standard animal housing, whereas maintaining adult chick-

ens and establishing a breeding program requires facilities designed for this purpose, and is necessarily a long-term project since the generation time is 6–12 months.

Chicken strains and genetic variability

Over a dozen highly inbred chicken strains, representing at least 10 of the approximately 30 characterized different MHC (B locus) haplotypes are available. Skin grafts between birds of the same inbred strain are permanently accepted, with the exception of female to male grafts, which are slowly rejected, hens being the heterogametic sex. MHC-congenic and recombinant haplotypes are available on some of the highly inbred backgrounds. Four μ chain, 10 γ chain and two light chain Ig allotypic variants are described, and Ig allotype-congenic and recombinant strains exist. Variation also occurs at non-MHC or Ig locus-linked loci of interest to immunologists, such as loci controlling blood group antigens or responsiveness to T cell mitogens.

With very few exceptions, the inbred strains are based on the White Leghorn type of domestic chicken. Attempts to inbreed other types of chicken or species of bird (ducks, Japanese quail) have been made, but have not generally been successful. There are lines of chickens with hypogammaglobulinemia resulting from abnormal bursal development, a line in which a disease similar to systemic scleroderma can be induced, and 'obese' chicken strains which develop a spontaneous autoimmune thyroiditis similar to Hashimoto's disease. Transgenic chickens can be produced by DNA transfer into fertilized eggs; viral vectors which can give high levels of somatic transgenesis are available. A chicken genome mapping project is under way.

Immune responses and tolerance

Chickens are generally good antibody producers, and their evolutionary distance from us enables them to

respond to some proteins (e.g. cytoskeletal elements) whose sequences are highly conserved in mammals. Immune responses develop early in chickens. They can respond to some protein antigens injected on the day of hatching, and in some cases to viruses or allogeneic or xenogeneic cells introduced into the egg. Responses to individual protein antigens develop at different times after hatching. As in mammals, IgM responses precede IgG; however, in some (but not all) antihapten responses, only poor affinity maturation is observed, consistent with the idea that there is not extensive generation of antibody variability in peripheral tissues (see below). Because of the difficulty of preparing monoclonal antibodies from chickens, their idiotypes and antibody repertoire have not been extensively studied.

Avian T cell-dependent responses (mixed lymphocyte reaction (MLR), skin graft rejection, delayed-type hypersensitivity given by cells injected into the wattle, responses to T cell mitogens) can be assayed essentially as for mammalian cells, while graft-versus-host reactions can be quantitated by the embryonic splenomegaly assay or by pock formation on the chorioallantoic membrane. T cell-dependent cytotoxic assays are established, and spleen cells from chickens infected with leukosis or reticuloendotheliosis viruses can kill infected target cells in an MHC-restricted, antigen-specific manner. Cytotoxic CD8⁺ cells play an important role in regression of some virally induced tumors.

Depending on the antigen and mode of injection, tolerance can be induced in chick embryos or newly hatched birds. Several interesting tolerance models have been studied. The antigens used include mammalian serum albumins (large doses given to newly hatched chicks lead to B cell tolerance, which is not suppressor cell dependent); quail embryo wing buds grafted into chick embryos (tolerance is induced only if a quail thymus is also grafted with the wing bud, and may be suppressor cell dependent); parabiosed allogeneic chick embryos (leads to tolerance in early embryos, but to development of leukemias and other abnormalities in later embryos); and allogeneic bursa cells injected into cyclophosphamide-treated 4-day-old chicks, leading to long-lasting and specific B cell chimerism. This model has been useful in studies of B cell development, requirements for T-B cell collaboration and antigen presentation by B cells.

Lymphoid organs

The development of B lymphocytes in a distinct primary lymphoid organ, the bursa of Fabricius, distinguishes the avian from other immune systems. Other differences between the lymphoid organs of

chickens and mammals are the multilobe structure of the bird's thymus, which consists of 6–7 distinct lobes on each side of the neck, making thymectomy technically difficult; the absence of organized lymph nodes in many avian species (they exist in a primitive form in ducks, but are replaced by numerous small lymphoid foci in chickens); the higher percentage of immigrant B cells in the avian than in mammalian thymus; the presence of a distinct gland (Harder's gland), located above the eye, which is full of plasma cells secreting IgM and IgA; and the presence of two appendix-like structures, the cecal tonsils, which branch from the gut and contain many lymphocytes. The thymus develops from an epithelial outgrowth of the pharyngeal pouches, and the bursa from an outgrowth of the cloacal epithelium starting at around day 5 of incubation. Epithelio-mesenchymal interaction is important in formation of the bursa. It has been postulated, but is not firmly established, that soluble factors (bursin, bursapoeitin, thymopoeitin) also play a role in genesis of these organs. Intrabursal B cell development is largely independent of exogenous antigens, although antigens introduced into the bursa can induce a local immune response in the bursal medulla.

Cells

B cell precursors located in embryonic mesenchyme enter the bursa between about days 8 and 15 of incubation. The presence of the Bu-1 antigen on at least some of these precursors (prebursal stem cells) suggests that they are already committed to the B cell lineage. Antibody variability is generated by gene conversion in the bursa (see below), probably until the organ involutes at sexual maturity. There is no evidence for development of B cells from Ig-negative precursors after hatching in any anatomical site. Instead, B cells arise in the bursa from Ig-positive bursal stem cells, and later in the periphery from postbursal stem cells, which can restore the peripheral, but not bursal B cell compartment after transfer to a cyclophosphamide-treated host. In their early formation and capacity for self-maintenance, chicken B cells differ from the majority of mouse and human B lymphocytes, although they do share some properties, e.g. CD5 expression, with the B-1 cells of these species. In spite of these differences, chicken B lymphocytes are functionally very similar to their mammalian counterparts in terms of capacity to differentiate into plasma cells and secrete antibodies at high levels. Chicken B cell subsets differing in surface phenotype and physiological criteria, such as mode of emigration from the bursa and turnover rate, have been described.

Chicken T cells develop from precursors which enter the thymus in several waves, starting at about day 6 of embryonic development, and formation of mature T cells appears to follow a course similar to that observed in mammals. Cells expressing $\alpha\beta$ T cell receptors (TCRs) have helper, cytotoxic or suppressor activities, and their functions, at least for helper and cytotoxic T cells, are MHC-restricted. Cells with a helper phenotype (carrying the CD4 antigen), as well as virally transformed CD8-bearing cells have been cloned. T cell-mediated suppression is most clearly shown in models where transfer of T cells from bursectomized birds into normal birds can induce B cell deficiency in the recipients; however, the mechanism of this suppression is not clear. Natural killer (NK) cell and antibody-dependent cellular cytotoxicity (ADCC) activities are readily detectable in chicken spleen and blood. Chicken NK cells have been identified as cytoplasmic CD3⁺, surface CD3/TCR⁻ and CD25⁺ cells. A subset of these cells expresses CD8 α .

Avian nonlymphoid hematopoietic cells (monocytes, granulocytes, thrombocytes, erythrocytes) are clearly defined morphologically and functionally, and bear characteristic cell surface markers detectable by monoclonal antibodies. All of these are nucleated cells, including the erythrocytes and thrombocytes, so that separation procedures designed for mammalian lymphocytes may need modification for avian cells.

In experiments involving cell or organ transfers, the types of cell marker used to follow cellular origin include strain- or species-specific monoclonal antibodies, the sex chromosome marker, and the quail-chick nuclear marker, useful because of its independence of cell cycle and lineage.

Proteins

The well-defined chicken Ig classes (IgM, IgA and an IgG-like class, also referred to as IgY) are functionally comparable to their mammalian counterparts. A truncated IgG/Y (IgY(Δ Fc)), derived by alternative RNA splicing, is found in ducks and geese. Whether a chicken IgD homolog exists is unclear. The chicken IgG/Y heavy chains have one more domain than mammalian γ chains and show about equal sequence homology to mammalian ϵ and γ chains. The IgG/Y molecules aggregate in high salt concentrations, a property which can be exploited to increase the sensitivity of assays dependent on immunoprecipitation. IgG/Y, but not IgM, is transported into the egg, from which antibody can be purified as readily as from serum. As in mammals, secretory IgA is polymeric and associated with a secretory component.

Chicken β_2 -microglobulin and MHC class Ia (B-F) and class II (B-L) molecules are structurally and functionally homologous to their mammalian counterparts. The β_2 -microglobulin is synthesized in the embryonic thymus around day 6 of incubation. B-F molecules are first detected on lymphoid and myeloid cells in 10- or 11-day embryos, and appear on erythrocytes around the time of hatching, whereas B-L molecules are first seen on bursal cells and macrophages about day 11 of incubation. A third type of polymorphic MHC product, B-G molecules, are disulfide-linked dimers of polypeptides which are not glycosylated and not associated with β_2 -microglobulin, and whose molecular weights vary in different strains between about 30 and 55 kDa. B-G molecules are present on the surface of embryonic and adult erythrocytes and their precursors, and on thrombocytes. On other cells, e.g. lymphocytes and intestinal epithelial cells, B-G or B-G-like antigens have also been detected. The function of B-G antigens is unknown, although they show some sequence homology to myelin oligodendrocyte glycoprotein and butyrophilin.

Chicken T cell surface components which resemble mammalian T cell TCR, as well as the CD3, CD4, CD5, CD6, CD8, CD28 and CD45 antigens and the interleukin 2 (IL-2) receptor α chain (CD25), have been identified. Sequence identities with the corresponding human homologs range from 23% (CD4) through 30–40% (CD3, 5, 8) to 50% (CD28). Three subpopulations of T cells, of which two carry $\alpha\beta$ and one $\gamma\delta$ TCR heterodimers, have been defined with monoclonal antibodies. Many (20–50%) peripheral T cells express $\gamma\delta$ TCRs. Monoclonal antibodies have also been used to characterize B and T cell surface markers without known functions or mammalian homologs, e.g. the Bu-1 (chB6) B cell allo-antigen and the chT1 cortical thymocyte antigen, as well as 'oncodevelopmental' antigens present, for example, on lymphoid tumor cells as well as immature (but not mature) normal erythrocytes.

Chicken IL-1, IL-2, interferon α/β , interferon γ and complement components C1, C3 and factor B of the alternative complement pathway have been characterized and resemble their mammalian counterparts. However, there is no evidence yet for a functional C2- and C4-mediated classical complement pathway in chickens. Fc receptors have been defined by their function on several cell types.

Genes

The Ig and MHC gene complexes of the chicken differ in interesting ways from their mammalian counterparts. In the case of the Ig light (λ) chains,

DNA rearrangement during embryonic development joins a unique functional V_L gene to a single J_L sequence adjacent to the single C_L gene. Light chain variability is generated principally by gene conversion (or a mechanism with similar effect), which leads to replacement of sequences in the rearranged V_L gene by sequences from one or more of a series of 25 V_L pseudogenes located 5' of the rearranged V_L . The whole light chain gene complex has been isolated, and all the pseudogenes as well as the functional V , J and C_L genes sequenced. A similar gene conversion mechanism generates heavy chain V region diversity, although in this case only 30 of an estimated 70 V pseudogenes have been sequenced (in addition to the single functional V_H , D and J_H regions and the unique C_μ and C_γ genes). D regions fused to the pseudogenes also contribute to variability. Recent evidence suggests that gene conversion and somatic point mutations additionally diversify the peripheral B cell repertoire in splenic germinal centers. As in mammals, the light and heavy chain gene complexes are not linked, whereas μ and γ chain genes are closely linked.

Chicken TCR α , β , γ and δ genes have been cloned and sequenced. As in mammals, δ and β genes comprise rearranged VDJC elements, whereas α and γ genes result from VJC rearrangement. There are only two V_α , two V_β , two V_δ and probably three V_γ families in chicken. The TCR α/δ locus organization is similar to that of mammals. Preliminary results indicate that both $V_\alpha 1$ and $V_\alpha 2$ gene segments can be used to encode TCR δ chains. The TCR repertoire is generated, in contrast to the B cell receptor repertoire, by combinatorial and junctional diversity, as in mammals.

The chicken MHC (B complex) is located on microchromosome 16, which carries the nucleolar organizer region (NOR). The B complex is smaller and simpler than mammalian MHCs. The average distance between genes in the complex is only about 10–20 kB, and typical intron sizes are about 100 bp. The class I α and class II β genes (two of each in the B complex of the B12 strain) are closely spaced, interspersed and G+C-rich. The single class II α gene is situated on the same microchromosome, some distance (about 5 cM) away from the MHC. In most MHC haplotypes there is a preferential expression of only one class I α and one class II β gene, although the number of expressed genes may be strain-dependent. Within the MHC, the BF/BL region containing class I α and class II β genes can be separated from a region encoding polymorphic B-G antigens, although the frequency of recombination between the two regions is low (about 0.05%). The B-G region contains multiple B-G genes, of which at least two are

transcribed and presumably give rise by multiple splicing, processing or other mechanisms to the multiple B-G products seen in protein analyses. At least one expressed B-G-like gene is also located within the B-F/B-L region. Other genes, one coding for a protein homologous to a G protein subunit, are also present in this region. In contrast to the mammalian situation, factor B polymorphism is not linked to the MHC in chickens.

Rfp-Y, a second region bearing MHC-type (two class I α and three class II β) genes, is also located on chromosome 16. It is separated from the B complex by a region which contains the NOR and exhibits frequent recombination. These MHC genes seem to be neither highly polymorphic nor highly expressed.

The chicken β_2 -microglobulin gene has been cloned and sequenced. It shows little polymorphism and is located on a large microchromosome (either 10 or 11).

Pathology

Diseases which specifically affect the avian immune system include the avian leukoses, Marek's disease and infectious bursal disease (IBD). The avian leukosis viruses (ALV) are closely related to the acutely transforming, *onc*-gene carrying viruses such as Rous sarcoma virus, which carries the *src* oncogene, and the replication-defective myelomacytosis viruses. The latter carry the *v-myc* oncogene and produce a spectrum of myeloid and lymphoid tumors. The ALVs do not carry their own oncogenes, but early studies of the slowly-transforming leukosis viruses showed that tumors developed in bursal cells when the virus was integrated next to the *c-myc* oncogene, leading to its aberrant activation, as in Burkitt's lymphoma cells. Reticuloendotheliosis viruses are also capable of inducing lymphomas in immunologically compromised birds, but are retroviruses not belonging to the ALV family. Marek's disease is caused by a very contagious DNA virus of the herpesvirus family. The virus infects both B and T cells, but specifically induces T lymphocyte transformation, and also leads to peripheral nerve degeneration, perhaps due to autoimmune attack. Resistance to Marek's disease is strongly correlated with presence of the B21 MHC allele, in both heterozygotes and homozygotes, and with low MHC class I antigen expression. Vaccination against the disease by infection of newly hatched chicks with a turkey herpesvirus is very effective, and provided the first example of a practical antitumor vaccine. The IBD virus is a double-stranded RNA virus which infects

bursal cells, producing extensive necrosis and immunodepression. An attenuated IBD vaccine is available.

Vaccines effective against other diseases of chicks exist: Newcastle disease (caused by an influenza-like virus), fowl pox and cholera, infectious bronchitis, avian encephalomyelitis, egg drop syndrome and coccidiosis, which is caused by a gut parasite. There is considerable interest in defining coccidial antigens which render birds immune after a single coccidial infection, since the current attenuated vaccine needs more care in storage and delivery than would a sub-unit-based vaccine. T cell clones with specificity for coccidial antigens have been cloned and in some cases shown to have helper activity *in vitro*. Defining the mechanisms of resistance to this and other avian diseases is currently an important task.

Medicine, Harvard Medical School, Boston, Massachusetts, USA

Two signals are required for optimal T cell activation. Specificity is provided by the interaction of the T cell receptor (TCR) with major histocompatibility complex (MHC)–peptide but a second, antigen-unrestricted costimulatory signal is also required. The B7 family of proteins, B7-1 (CD80) and B7-2 (CD86 or B70) provide the major costimulatory signal for T cell activation and clonal expansion via their interaction with CD28. Engagement of

the TCR in the absence of B7 costimulation results in T cell clonal anergy.

Structure

B7-1 and B7-2 are type I membrane proteins with an extracellular domain consisting of one immunoglobulin V (IgV)-like and one IgC-like domain, followed by a transmembrane anchor and short cyto-

plasmic tail. Mature B7-1 has 254 amino acids, is heavily glycosylated, and has a molecular weight of 45–70 kDa. Mature B7-2 has 304 amino acids, is heavily glycosylated, and has a molecular weight of 60–100 kDa. The genes for both B7-1 and B7-2 are located on human chromosome 3q21 and mouse chromosome 16B5.

Both B7-1 and B7-2 are counter-receptors for CD28, expressed on resting as well as activated T cells, and for CTLA4 (CD152), expressed on activated T cells. Dimeric CD28 has equivalent low avidity for both B7-1 and B7-2 (2400 nM) but dimeric CTLA-4 has a greater than 400-fold higher avidity for B7-1 than B7-2 (1 and 4 nM). Both B7-1 and B7-2 have very fast on/fast off rates but the binding kinetics differ, with B7-1 binding and dissociating more slowly.

B7-1 and B7-2 bind to the same general region on CD28 and CTLA4 but the amino acids critical for B7-1 or B7-2 binding are different. The CDR3 loop of the IgV-like domain of CD28 and CTLA4 contains a conserved MYPPPY motif (amino acids 99–104) important for both B7-1 and B7-2 binding. Tyrosine 104 is critical for binding to both B7-1 and B7-2. Residues 100, 99, 101 and 102 are important for differential binding of B7-1 versus B7-2.

Though B7-1 and B7-2 have similar structures, their extracellular domains have only 27% amino acid identity and other regions are even less conserved. B7-1 and B7-2 function well across species, suggesting that the ligand binding site is highly conserved. Conserved residues on the GFCC'C" face of the B7 IgV domain and on the ABED face of the B7 IgC domain are important for binding. The eight N-linked glycosylation sites of B7 are on the opposite side from the B7/CD28 interaction surface and do not contribute to binding. Thus, CD28 and CTLA4 use sequences in their CDR3 and CDR1 regions, much like antibodies, to bind to a surface on the side of the B7 IgV and IgC domains.

Expression

B7 expression is tightly regulated and mainly restricted to antigen presenting cells. B7 on the cell surface is a monomer but is locally concentrated in small foci. B7-2 is constitutively expressed on unstimulated dendritic cells and blood monocytes. B7-1 is generally absent from unstimulated cells. B7-1 mRNA transcription is regulated by a cell-type specific enhancer responsive to NF κ B family members. B7 expression is upregulated by 'danger' signals such as bacterial DNA or lipopolysaccharide and by the innate immunity receptor, Toll. On dendritic cells, both B7s are rapidly upregulated by granulocyte-

monocyte colony-stimulating factor (GM-CSF) or CD40L/CD40 signaling. On monocytes, B7 levels are increased by interferon γ (IFN γ). Unstimulated human B and T cells do not express B7. B7-1 and B7-2 are induced in B cells by cross-linking of CD40, surface Ig, or MHC class II, and by interleukin-2 (IL-2), IL-4, IL-5, tumor necrosis factor α (TNF α) and lymphotoxin (TNF β). Memory B cells constitutively express B7-1 and B7-2 and rapidly upregulate them, permitting memory B cells to rapidly activate T cells. B7-1 and B7-2 are induced in T cells following activation and are upregulated by IL-7. Other cells also can express B7, including IFN γ -treated fibroblasts (B7-1), vascular endothelial cells (B7-2), IFN γ -treated astrocytes (B7-2) and gastric epithelial cells. Adjuvants (e.g. Freund's adjuvant, Neisserial porins) strongly induce B7 expression, providing an important mechanism for their stimulation of an immune response. Generally, B7-2 is expressed more rapidly and at higher levels than B7-1. B7-2 is expressed at sites of inflammation and B7-1 expression is found when chronic inflammation progresses to tissue damage.

B7 expression is downregulated by IL-10, transforming growth factor β (TGF β), ultraviolet light, the environmental toxin, dioxin, and cross-linking of the low-affinity IgG receptor, CD32, by immune complexes. Microorganisms (e.g. *Leishmania donovani*, *Mycobacterium tuberculosis*) can inhibit B7 expression. These agents are immunosuppressive, presumably in part because they reduce B7 costimulatory signals.

Function

The B7/CD28 pathway is important for cellular and antibody responses to viral and microbial infections, cancer, graft rejection and the development of autoimmunity. During antigen presentation, B7 bound to CD28 or CTLA4 coassociates on the cell surface with MHC-peptide bound to TCR in the activation cap between T cell and antigen-presenting cell (APC) but engages a distinct signaling pathway. For B7-1, this colocalization depends on the short but highly positively charged cytoplasmic tail which interacts with cytoskeletal components.

Binding of B7 to CD28, in conjunction with a TCR signal, stimulates production of multiple cytokines, including IL-1, 2, 3, 4, 5, 6, 8, 10, 13, TNF α , TNF β , GM-CSF, CSF-1 and IFN γ . B7/CD28 signaling upregulates expression of growth factor receptors including α , β and common γ chain of the IL-2 receptor. B7/CD28 signaling upregulates chemokines (MIP-1 α , MIP-1 β and RANTES) and chemokine receptor CXCR4, but downregulates expression of

chemokine receptors CCR1, CCR2a, CCR2b and CCR5. B7/CD28 interaction stimulates production of the anti-apoptotic proteins bcl-x_L and bcl-2, leading to enhanced T cell survival and upregulates telomerase expression, thereby contributing to T cell clonal expansion. B7/CD28 interaction activates cyclic AMP-responsive element-binding protein which regulates proliferating cell nuclear antigen, DNA polymerase δ and cyclin A. While some of these proteins can be induced by a strong TCR signal alone, B7/CD28 signaling greatly hastens and augments the level of expression. B7/CD28 interaction lowers the threshold for T cell activation by approximately 2 logs of antigen concentration and is thus most important for low antigen doses and weaker antigens. Nevertheless, B7/CD28 interactions are not essential for T cell activation as strong TCR signaling alone can activate T cells. While B7 can prime T cells, it is not essential for T cell priming. B7/CD28 interactions are critical for T cell clonal expansion, high-level lymphokine production, and T cell help for B cells.

The B7/CD28 and CD40/CD40L pathways cross-talk to reinforce immune activation. CD28 signaling induces CD40L expression and CD40 signaling induces B7 expression, and in dendritic cells and macrophages also induces IL-12 secretion. The cross-talk and synergistic function of these pathways is supported by the observations in some transplant models which show that optimal tolerization is achieved by blockade of both the B7/CD28 and CD40/CD40L pathways.

B7/CD28 interaction is also critical for the differentiation of precursor CD8 T cells into cytolytic effectors and induces cytolytic proteins such as granzyme B. Following the development of cytolytic effectors, B7 expression is not needed on the target cell for cytotoxic T lymphocyte killing.

CTLA4-Ig, a fusion protein in which the extracellular domain of CTLA4 is fused to IgG, binds to B7-1 and B7-2, and is a potent blocker of immune responses. While high concentrations of CTLA4-Ig completely inhibit both B7-1 and B7-2 mediated costimulation, lower concentrations inhibit B7-1 but not B7-2-mediated responses.

CTLA4-Ig or a combination of anti-B7-1 and B7-2 monoclonal antibodies (mAbs) have shown great promise in blocking autoimmune disease or tolerizing for transplantation. CTLA4-Ig or anti-B7-1 and B7-2 mAbs have been used to tolerize successfully for pancreatic islet cell xenotransplants, heart transplants and bone marrow transplants. Following cessation of CTLA4-Ig treatment, donor antigen-specific tolerance is seen. The mechanism for this tolerance is hypothesized to be T cell clonal anergy.

A competent immune response to other antigens and infections remains.

B7-2 is the major costimulator for initiating both T_{H1} and T_{H2} immune responses because of its constitutive expression and more rapid upregulation. The need for two B7 proteins is unclear but many studies with murine models of autoimmunity show different effects of blocking B7-1 or B7-2. Whereas complete blockade with CTLA4-Ig or anti B7-1 plus anti-B7-2 mAbs prevents the development of disease in murine models of nonobese diabetes (NOD), systemic lupus erythematosus (SLE) and experimental autoimmune encephalitis (EAE), and alleviates symptoms in established disease, different effects are seen when either B7 is blocked. In NOD and SLE, anti-B7-2 mAb is sufficient to alleviate disease but in NOD, anti-B7-1 mAb alone exacerbates disease. In contrast, anti-B7-1 mAb alleviates EAE, whereas anti-B7-2 mAb exacerbates EAE. B7-1 is a more effective costimulator for weak peptide ligands and this may explain the importance of B7-1 in the progression of autoimmunity to subdominant epitopes.

Alternatively, these differences may be due to timing of expression, as, in NOD and SLE, B7-1 and B7-2 are regulated by normal genetic mechanisms but, in EAE, B7-1 and B7-2 are artificially upregulated by adjuvant. Differences in function also may be due to differences in strength or quality of signal delivered upon binding to CD28/CTLA4. B7-1 and B7-2 can equivalently stimulate IL-2 and IFN γ production, however, the level of IFN γ is only moderate, with IL-12 being critical for the high-level IFN γ production characteristic of T_{H1}. B7-2 costimulation along with antigen concentration and affinity are important for the differentiation of naive T cells into the initial producers of the IL-4 that primes for further IL-4 synthesis. Three studies show that B7-2 more effectively induces IL-4, but two others find that B7-1 and B7-2 induce IL-4 equally. However, after T_{H2} differentiation, a TCR signal alone can be sufficient for IL-4 production. B7/CD28 signaling also regulates proliferation of T_{H2} cells via the induction of IL-1 which makes T_{H2} cells responsive to IL-4.

Studies on antibody production using mice lacking both B7-1 and B7-2 show a loss of germinal center formation and reductions in IgG1 (IL-4 dependent) and IgG2a (IFN γ dependent) of 99% and 95%, respectively. Deletion of B7-1 alone has no effect on antibody production, whereas deletion of B7-2 alone results in a loss of IgG production when mice are immunized in the absence of adjuvant. When B7-2 deficient mice are immunized in the presence of adjuvant, which induces B7-1, IgG levels are normal. These studies show that if it is induced, B7-1 can

replace B7-2 in stimulating help for antibody production.

Productive infection by human immunodeficiency virus (HIV) requires activated memory CD4 T cells. Blockade of B7/CD28 prevents HIV transmission in an *in vitro* T cell/dendritic cell system. CD28 signaling promotes viral cDNA synthesis, transport of viral DNA to the nucleus, and provirus expression, and enhances HIV-Tat protein-mediated IL-2 production. CD28 signaling upregulates expression of CXCR4, the T-tropic fusion coreceptor, but not CCR5, the macrophage-tropic coreceptor. Progression of HIV-infected individuals to the acquired immune deficiency syndrome (AIDS) is associated with loss of M-tropic strains and appearance of T-tropic strains. Before progression, *in vitro* expansion of T cells from HIV-infected individuals with anti-CD3 and anti-CD28 mAbs leads to loss of HIV through downregulation of CCR5, and production of MIP-1 α , MIP-1 β and RANTES, and provides a source of healthy T cells. However, following progression to a T-tropic strain of HIV, CD28 stimulation might increase virus load. Using HIV antigens and either B7-1 or B7-2 in naked DNA vaccines, B7-2 but not B7-1 stimulated both cytotoxic T lymphocyte and delayed-type hypersensitivity responses against HIV antigens in mice.

Tumors generally do not express costimulatory molecules. The B7 gene has been transfected into tumor cells in the hope that the tumor cells will gain costimulatory function and stimulate an antitumor response. Many B7-transfected tumor cell lines are rejected by their host. When an animal that has rejected a B7⁺ tumor is challenged with parental tumor not expressing B7, the tumor is rejected, demonstrating that B7 can stimulate antitumor immunity. Immunity is best induced by live B7⁺ tumor cells and is primarily CD8 T cell mediated. B7-transfected tumor cells can stimulate a successful immune response against established wild-type tumor if the tumor burden is small. Some studies find that B7-1 and B7-2 equivalently stimulate antitumor immunity, whereas others report that B7-1 is more effective.

CTLA4 has a greater than 400-fold higher avidity for B7 than does CD28 but is expressed only after T cell activation and at only 2–5% of the level of CD28 cell surface expression. In contrast to the stimulatory signal delivered by B7/CD28 interaction, the B7/CTLA4 interaction results in a downregulatory signal leading to inhibition of IL-2 production and cell cycle progression and to T cell death. An mAb with dual specificity that recognizes a common epitope shared by CTLA4 and CD28 positively stimulates T cell proliferation, suggesting that

B7/CD28 signaling dominates over B7/CTLA4 signaling.

The differing avidities of B7 for CD28 and CTLA4 and their highly regulated temporal expression has led to a model in which moderate levels of B7 engage CD28 on resting T cells and costimulate T cell activation. Following activation, the T cell expresses CTLA4 and CD28, and with moderate to high levels of B7, both are engaged, with the stimulatory CD28 response dominating. As B7 expression declines to low levels, all available B7 is engaged by higher avidity CTLA4 and CTLA4 signaling leads to downregulation of the T cell response.

BABESIOSIS

Jeffrey A Gelfand and **Michael V Callahan**, Department of Medicine, Tufts University School of Medicine, Boston, Massachusetts, USA

Babesiosis is a malaria-like disease transmitted by parasitized ticks of the genus *Ixodes* during blood feeding. There are over 100 species of *Babesia* which, with *Theileria*, comprise the family Piroplasmorida. Both adult and nymph stages of the *Ixodes* ticks (*I. scapularis*, *I. pacificus*, *I. ricinus*) transmit the disease from reservoir competent-species, principally rodents, to humans (Figure 1). The rodent strain, *Babesia microti* (in the United States), and the cattle strains, *B. divergens* and *B. bovis* (in Europe), are responsible for the majority of human cases. Conditions favorable for human infection include presence of disease reservoir species (rodents), of suitable hosts for blood feeding (deer, cattle) and proximity to human populations. Disease transmission through blood products and transplacental and possible perinatal infection have been described. In the United States, the majority of cases occur in the Northeast, upper Midwest and Pacific Northwest. Recently, a new species of *Babesia*, designated WA-1, has been implicated in human babesiosis in Washington and northern California. Phylogenetic analysis of DNA isolated from this species demonstrates greater similarity with *B. gibsoni*, a canine form, and to theileria species than to species known to infect humans. A fatal case of babesiosis has also been reported from Missouri. The isolate, designated MO-1, was found to have antigenic similarities and ribosomal DNA

sequences similar to *B. divergens*, a strain that causes disease in cattle and humans in Europe.

Infection with the murine strain, *B. microti*, is typically a mild illness in healthy people; however, in the asplenic or immunocompromised patient, such as those with AIDS, lymphoma or transplant patient, the disease may be overwhelming. Infection with bovine strains *B. divergens* and *B. bovis*, as seen in Europe, occurs in asplenic patients and is often fatal. Initial symptoms of babesiosis are nonspecific and include fever, chills, nausea, vomiting, arthralgia, myalgia, headache, fatigue and dark urine. The presence of a rash similar to erythema chronicum migrans probably reflects simultaneous infection with *Borrelia burgdorferi*, which is transmitted by the same vector. Laboratory studies may show decreased haptoglobin, elevated reticulocytes and parasitized red cells on blood films. Leukocytosis is rare; however, thrombocytopenia is common. Patients often have a positive direct Coombs test, and urine studies reveal proteinuria and hemoglobinuria. Liver function tests often show mild elevations of alkaline phosphatase, serum bilirubin, aspartate transaminase, alanine transaminase and lactate dehydrogenase. Successful treatment involves combination drug therapy with clindamycin plus quinine, or atovaquone plus azithromycin. Emergence of resistant strains has been documented following monotherapy. Life-

Figure 1 Life cycle of *Babesia*. The parasite requires the presence of *Ixodes* ticks, a reservoir-competent host animal such as rodent species, and large mammals for nymph and adult stages of the tick. Human infection occurs following the bite of infected nymph or adult ticks.

threatening cases may benefit from exchange blood transfusion.

The pathogen

After passage from the salivary glands of the tick into the vertebrate bloodstream, sporozoites penetrate and infect host erythrocytes (Figure 1). Following infection, *B. microti* undergo asynchronous, asexual budding and divide into two or four merozoites (daughter cells) (Figure 2). Intraerythrocytic merozoites often appear in a ring form morphologically similar to *Plasmodium falciparum*, which has resulted in diagnostic confusion (Figure 3). Infection by the rodent species, *B. rhodaini*, has been shown

to involve the alternative complement pathway and the C3b receptor on rat erythrocytes. The parasite activates complement and fixes C3b to its surface, which in turn binds to the rat erythrocyte C3b receptor, leading to intracellular infection. Additionally, erythrocytes with C3 on their surface are infected, thus suggesting that complement facilitates the parasite-erythrocyte interaction. Following intracellular maturation, merozoites exit the erythrocyte, resulting in perforations and damage to the red cell membrane. The actual mechanism of hemolysis is unknown. Circadian hemolysis from synchronous schizogony, typified by the cyclic fevers of *Plasmod-*

Figure 2 Giemsa-stained thin blood film. Four mature merozoites form the 'tetrad' or 'Maltese cross' prior to schizogony (single arrow). (Courtesy of Philip R. Daoust MD.)

ium infection, does not occur because schizogony is asynchronous.

Host response to babesia is poorly understood; however, the spleen is known to play a central role in immune defense. Asplenic patients and animals are more susceptible to infection by babesia and have increased parasitemia. Splenectomy and steroid therapy in animals and patients that have recovered from babesiosis may result in recrudescence of disease. As blood percolates through the spleen it is in close contact with splenic endothelium, macrophages and macrophage products. Erythrocytes must squeeze through intraendothelial spaces. Infected, deformed and potentially more rigid infected erythrocytes are more likely to be retained, where ingestion by macrophages or the action of macrophage products may serve to control the infection. Complement-sensitized erythrocytes would likely bind under these circumstances. Furthermore, complement activation by babesia could theoretically lead to the generation of tumor necrosis factor α (TNF α) and interleukin-1 (IL-1), enhancing local defense. Decreased complement levels, presumably secondary to activation, are frequently found in babesiosis. In addition, increased circulating C1q binding activity, presumably due to immune complexes, with a commensurate decrease in C4, C3 and CH50 levels, are seen in patients. The generation of these primarily macrophage-produced mediators (TNF α and IL-1) in turn could explain many of the clinical features (fever, anorexia, arthralgias, myalgias) of babesiosis, especially the fulminant shock syndrome of bovine babesiosis. It is likely that, in the less fulminant situation, TNF α functions to enhance the killing of *Babesia*, as with malaria. In addition to macrophage factors, other cellular immune functions appear to be important in the host response to *Babesia*. Nude mice and mice with greatly reduced T lymphocyte responses due to thymectomy, lethal irradiation or anti-T-lymphocyte serum develop significantly greater parasitemia. The disease itself alters cellular immune function. Patients with acute babesiosis have an increase in T suppressor/cytotoxic lymphocytes and decreased responses to lymphocyte mitogens with a polyclonal hypergammaglobulinemia.

BACILLUS, INFECTION AND IMMUNITY

Brian W McBride and Peter CB Turnbull, Centre for Applied Microbiology and Research, Porton Down, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

The best known member of the genus *Bacillus*, *Bacillus anthracis*, the causative agent of anthrax, was a major scourge for humans and animals from antiquity to just a few decades ago. The extensive history associated with anthrax dating back to about 1250 BC has been well reviewed. It features in classical writings, and several pandemics evidently occurred in Europe and Russia from medieval times to the mid-1800s. By the time it was realized at the end of the nineteenth century that one agent was responsible for several manifestations, the disease had become known by a wide variety of names, such as black bane, malignant carbuncle, rag picker's disease, Siberian plague, woolsorter's disease and numerous equivalents in other languages. It was with anthrax that Koch established his famous postulates in 1876, and history's first bacterial vaccines were against anthrax.

Other members of the genus only began to feature in literature in the early part of the twentieth century and, because of the extreme diversity of the species comprising it, organization of the taxonomy and classification within the genus has only developed very slowly and remains a challenge for today's taxonomists. For most practical purposes, the classification and identification system laid down by Gordon and colleagues in 1973 continues to be the most helpful for the principal species encountered in the context of infection and immunity.

Description and distribution of the genus

The family Bacillaceae comprises the rod-shaped bacteria which form endospores. The two principal subdivisions are the anaerobic spore-forming bacilli of the genus *Clostridium* and the aerobic or facultatively anaerobic endospore formers constituting the genus *Bacillus*. Familiarly known as aerobic spore-bearing bacilli (ASB), they are gram positive or gram variable and the majority are motile by peritrichous flagella. The endospores, one per vegetative mother cell, are resistant to adverse physical and chemical conditions. They are mostly saprophytes, having a wide diversity of physiological characteristics, which, together with their ability to form hardy spores, enables them to be widely distributed in nature from Arctic environments to hot springs and desert sands and from fresh water to salt or marine sediments.

Thermophilic and psychrophilic, acidophilic and alkaliphilic, and halophilic representatives exist which are capable of growing at extremes of temperature, pH or salt concentration that would inhibit or destroy life processes in other living organisms. The spores are dispersed in dust, water and on materials of plant or animal origin.

Importance

As a result of their wide-ranging physiological characteristics and the myriad of enzymes, antibiotics and other metabolites they elaborate, *Bacillus* species are important in a host of medical, agricultural, pharmaceutical or other industrial applications and processes. Among the better known antibiotics are bacitracin from *B. licheniformis* or *B. subtilis*, polymyxin from *B. polymyxa* and gramicidin from *B. brevis*. Several are important in antibiotic assays (*B. pumilus*, *B. cereus*, *B. stearothermophilus*) or other health-related assays, e.g. folic acid (*B. coagulans*), aflatoxin (*B. megaterium*) and hexachlorophene (*B. subtilis*). Certain *Bacillus* species are utilized for degradation of pollutants and waste materials. One strain of *B. cereus* is the active ingredient of an antidiarrheal formulation prescribed in certain countries of Europe. The spores of the thermophilic *B. stearothermophilus* are particularly well suited to checking heat sterilization procedures for laboratory, surgical, pharmaceutical and food preservation processes, and *B. subtilis* var *globigii* (NCTC 10073), having a high resistance to heat, radiation and chemical disinfectants, is used for validating alternative sterilization and fumigation procedures. Contrariwise, the resistance of spores to heat, radiation, disinfectants and desiccation results in *Bacillus* species being troublesome contaminants in pharmaceutical products, foods, surgical theatres and dressings, etc. *B. thuringiensis*, *B. popilliae*, *B. sphaericus*, *B. larvae* and *B. lentimorbus* are insect pathogens. The first three are utilized in commercial insecticides for controlling crop-destroying and disease-carrying insects; *B. thuringiensis* has the widest use in this context, providing control of an extensive range of pests on many different crop types.

Bacillus species and diseases

That the etiological agent of anthrax is a *Bacillus* species, namely *B. anthracis*, was mentioned at the outset. The pathogenic potential of ASB other than *B. anthracis* has become increasingly recognized in the past three decades with a proliferation of reports implicating *Bacillus* species, particularly *B. cereus*, in distinct emetic and diarrheal types of food poisoning and in infections of immunocompromised or otherwise debilitated hosts (e.g. alcoholics, diabetics), in mixed or secondary infections or occasionally in primary infections in otherwise healthy humans or animals.

Species in addition to *B. anthracis* that have been implicated on one or more occasions in published reports on infections are *B. cereus* (numerous reports), *B. licheniformis* and *B. subtilis* (several reports), *B. alvei*, *B. brevis*, *B. circulans*, *B. coagulans*, *B. macerans*, *B. pumilus*, *B. sphaericus* and *B. thuringiensis* (a few reports). Among the types of infection involved apart from food poisoning are bacteremia/septicemia, endocarditis, meningitis, ophthalmitis, respiratory and urinary tract infections and severe wound infections.

Virulence factors in anthrax

Bacillus anthracis depends for its virulence on two factors: 1) a polypeptide (poly- γ -D glutamic acid) capsule protecting it from phagocytosis, and 2) a toxin comprised of three protein components termed protective antigen (PA – 83 kDa), lethal factor (LF – 90 kDa) and edema factor (EF – 89 kDa). By the currently accepted model, PA binds to host cell surface receptors and is activated by a host cell protease, furin, which cleaves off a 20 kDa piece, thereby exposing a secondary receptor site for which LF and EF compete to bind on the active PA (PA63). Complexes of PA + LF (lethal toxin) or PA + EF (edema toxin) are then internalized, apparently in heptameric complexes, by receptor-mediated endocytosis, with the LF or EF being released into the cytosol from the endosome following acidification. There is some analogy here to the A–B complex of cholera toxin, with EF and LF acting as alternate ‘A’ (active) moieties competing for the same entry mechanisms and with PA as the ‘B’ (binding) moiety, with PA probably creating ion-conductive channels across the eukaryotic cell membrane through which LF and EF gain access to the interior of the cell. Edema factor is a calmodulin-dependent adenylate cyclase (calmodulin only being present in eukaryotic cells). The only other known bacterial adenylate cyclase toxin component is that of *Bordetella pertussis* but

the two do not appear to be closely related structurally, genetically or antigenically, although some genetic and antigenic homologies have been noted.

LF appears to be a calcium- and zinc-dependent metalloenzyme. It is generally believed that the LF + PA complex is the major cause of tissue damage and death, with systemic shock and death seemingly resulting from the effects of high levels of cytokines (see below).

The precise kinetics of production of PA, LF and EF are not known; they appear to be elaborated concurrently and can be detected in cultures from early log phase onwards. Virulence differences among strains have not been associated with differences in quantity or rate of toxin production by different strains, and the toxin from different strains appears identical in all respects – attributable to it being encoded on a plasmid. The origin of the toxin components in the *B. anthracis* cell has not been elucidated.

The two virulence factors of *B. anthracis*, toxin and capsule, are genetically encoded on two large plasmids, respectively pX01 (175 kb) and pX02 (90 kb). The genes for each of the toxin components *pag*, *lef* and *cya* and for the membrane associated enzymes mediating D-glutamic acid polymerization have all been sequenced.

Pathogenesis and host resistance in anthrax

Lethal toxin (LF + PA) and edema toxin (EF + PA) are now regarded as being responsible for the characteristic symptoms and course of anthrax. LF + PA is cytolytic for mouse peritoneal macrophages and kills certain mouse macrophage cell lines; EF + PA impairs the phagocytic function of neutrophils but EF + PA, LF + PA, or EF + LF + PA stimulate neutrophil chemotaxis.

There has long been fascination over the seemingly inverse relationship between susceptibility to toxin and susceptibility to infection. Rats, for example, are highly susceptible to the toxin (LD_{50} (median lethal dose) of Fischer 344 rat = 0.5 μ g LF + $\approx$ 2.5 μ g PA) but highly resistant to the infection (intramuscular LD_{50} $\sim$ 10^6 spores), while guinea pigs are relatively resistant to the toxin (LD_{50} = 50 μ g LF + $\approx$ 250 μ g PA) but highly susceptible to infection (intramuscular LD_{50} < 10 spores). The underlying host defense mechanisms responsible for this paradox have not been elucidated but it indicates that resistance to infection may involve a separate mechanism than that required for resistance to lethal toxicity. If resistance to infection is due to the number and availability of macrophages then this protective

mechanism would also provide a larger target population of macrophages for the effect of LF toxin.

The *in vivo* depletion of mouse macrophages by the use of repeated injections of silica has elucidated the key role macrophages play in the disease process. BALB/c mice depleted of macrophages are resistant to lethal toxin (LT) but can be made sensitive to it by adoptive transfer of 10^8 RAW264.7 cells (a toxin-sensitive monocyte/macrophage cell line). The *in vivo* transfer of the same number of the LT-resistant mouse macrophage line IC-21 cells does not restore sensitivity. Resistant cells have been shown to possess normal numbers of receptors for PA and are able to activate PA and bind and internalize LF and EF. In addition, introduction of LF into the cytosol of resistant cells does not result in cell death, indicating that these cells may lack the cytosolic target of LF. Genetic studies involving resistance to nonencapsulated bacilli indicate that resistance may be controlled by a single dominant locus or gene complex.

Analysis of cytokine levels produced by RAW264.7 cells *in vitro* has revealed that levels of LT as low as 10^{-9} $\mu\text{g ml}^{-1}$ LF with 0.1 $\mu\text{g ml}^{-1}$ PA induce synthesis of high levels of tumour necrosis factor (TNF) and interleukin-1. Neutralizing antisera to each of these cytokines injected into mice 24 hours before challenge with LT provides partial protection, while complete protection is achieved when the antisera are combined. These results strongly implicate the release of these factors in the cause of death of toxin-treated animals by a septic shock-type mechanism. Whether this and differences in susceptibilities of macrophages to LF + PA/EF + PA are related beyond mouse models to inter- and intraspecies differences in susceptibility to *B. anthracis* or its toxin remains to be determined.

Virulence factors and pathogenesis of other *Bacillus* species

The state of knowledge on virulence factors of *Bacillus* species other than *B. anthracis* is less advanced owing to the relatively spasmodic association between these species and infections and to the absence of adequate models for analyzing the candidate factors and determining their actions in the laboratory.

Bacillus species characteristically produce a host of enzymes and other extracellular metabolites. Among those of *B. cereus*, four groups of what are broadly described as toxins have been distinguished and most of these are believed also to be virulence determinants in infections. These are:

- 1 Three phospholipases C (alias lecithinase, egg-yolk turbidity factor), phosphatidylcholine

hydrolase (23 kDa), phosphatidylinositol hydrolase (phosphatase factor, 29 kDa) and sphingomyelinase (29 kDa). Although under normal *in vivo* circumstances they cannot reach their phospholipid substrates in the eukaryotic cell membrane, they may conceivably act secondarily after exposure of the phospholipids in wounds or other infections. Sphingomyelinase is also hemolytic.

- 2 Hemolysin I (alias cereolysin), a thiol-activated thermolabile protein cytotoxin with a single 518 amino acid polypeptide chain of 55 kDa. The binding-site of the thiol-activated cytotoxins on the eukaryotic cell membrane is cholesterol and binding results in pitting and micropuncturing of the cell membrane, leading to loss of control of ion exchange. The net flow of ions and water into the cell leads to swelling and rupture. However, cereolysin is inactivated by free cholesterol in the blood, which presumably limits its activities in natural infections. It is almost instantly lethal on intravenous injection in mice and causes necrosis if injected into skin.
- 3 Hemolysin II (HBL), consisting of a protein (component B, 36 kDa) which binds to or alters cells, allowing subsequent lysis by a second protein (component L, 45 kDa). This appears also to be the necrotic enterotoxin responsible for diarrheal-type *B. cereus* food poisoning and occasional severe wound, eye and other infections. It is almost instantly lethal if injected intravenously in mice; unlike cereolysin, this activity is not neutralized by cholesterol.
- 4 Emetic principle. This is a highly stable, small molecular weight entity, or group of entities, capable of surviving extremes of heat and pH and not susceptible to proteolytic enzymes. It may be associated with breakdown products from the implicated food, although it has recently been proposed that it is now identifiable as 'cereulide', a novel dodecadeptide.

The protein cytotoxin enterotoxin identified by Japanese workers in 1991 may represent a fifth group. The different toxins appear to be produced to different extents by different strains, which may account for the varying degrees of seriousness of *B. cereus* infections.

Toxins have not been demonstrated in culture fluids or extracts of other *Bacillus* species periodically implicated in infections and, assuming they did play active roles in the infections from which they were isolated, the basis of their pathogenic activity is not clear.

Acquired immunity: vaccines

The polypeptide capsule of *B. anthracis* is only weakly antigenic and there is little evidence to suggest it contributes to naturally acquired immunity or can produce artificially induced protection against anthrax. Pasteur derived his vaccine strains by subculturing at 42–43°C and was inadvertently curing the bacilli of pX01. However, cap⁺/tox⁻ strains are, in fact, not protective and both the partial efficacy and the residual virulence of Pasteur's vaccines are now explained in terms of mixed cultures with residual uncured forms. Cap⁻/tox⁺ strains of *B. anthracis* are protective and one such strain, produced by Sterne in 1937, has remained to this day the basis of a highly successful live-spore animal vaccine, although this vaccine too retains some residual virulence in certain susceptible species (albeit considerably less than wild type tox⁺/cap⁺ *B. anthracis*), such as guinea pigs, a number of inbred strains of mice and certain livestock species, notably goats and llamas. As a result of this, it is considered unsuitable in the West for use in humans, although a live-spore vaccine similar to the animal vaccine is administered by scarification to people in the countries of the former USSR and in China. In the West, human vaccines developed in the 1950s and 1960s are available and consist essentially of aluminum hydroxide-adsorbed cell-free filtrates of cultures of a noncapsulating, nonproteolytic derivative of strain V770 originating from a case of bovine anthrax in 1951 (US vaccine) and alum-precipitated cell-free filtrates of Sterne strain cultures (UK vaccine). Several doses are required, however, for these to take effect and the results of animal tests suggest it may be possible to improve their efficacy; attempts are now being made to do this using the rapidly expanding knowledge of what is and what is not needed for protection.

With recently acquired techniques for purification and genetic manipulation of the toxin components, it has become clear that immune responses to PA, but not to LF or EF, are essential for protection. However, studies have also indicated that, while antibody responses to EF and LF are weak in mice immunized with spores of *B. anthracis* strains capable of only producing either EF or LF, immunization with strains producing either PA or EF or PA and LF resulted in higher antibody responses to EF or LF, respectively. In addition, studies have indicated a synergistic relationship between PA and LF or EF in immunoprotection. These results may indicate a requirement for EF and LF to be internalized, via PA, and intracellularly processed in order to produce substantial antibody responses. Notwithstanding this, the protection induced by PA alone can be

raised to levels equivalent to and as long-lasting as that conferred by the live-spore vaccine if purified PA is administered together with killed whole-cell microbial supplements such as Freund's complete adjuvant, *Bordetella pertussis* or *Corynebacterium ovis*, or complex cell wall extracts from the tubercle bacillus ('Tri-Mix' and 'De Tox', Ribi ImmunoChem Research, Hamilton, Montana, USA). This nonspecific stimulation of protection indicates involvement of some cellular immune mechanisms – more than that simply produced by inciting a coincidental inflammatory response as the performance of PA is not enhanced by an irritant such as saponin.

To date, PA is the only antigen shown to induce substantial protective immunity. Studies on monoclonal antibodies directed against PA, which neutralize lethal toxin activity, either *in vivo* or *in vitro*, have identified at least three nonoverlapping antigenic regions. Two of these regions are involved in the binding of LF to cell-bound PA (the first region mapping between amino acids Ile581 or Asn601 and the second within the PA17 fragment produced by limited chymotrypsin digest of PA63). The third region is involved in the binding of PA to cells and maps between amino acids Asp671 and Ile721 of the carboxy-terminus of PA. The elucidation of the protective motifs on PA may eventually lead to the introduction of a subunit-based vaccine. The relationships between the toxin, the development of the characteristic massive bacteremia of anthrax and the mechanism by which antibodies to PA, a log phase metabolite, prevent this bacterial multiplication, remain to be elucidated. The development of a vaccine dependent on an antigen apparent to the immune system at the outset of the infection, rather than during the log phase of growth, appears to be unachievable.

Passive immunity was tried in Europe in the early part of the twentieth century in the treatment of anthrax but was discontinued many years ago as being of negligible value. In the light of modern plasmapheresis technology, it may be appropriate to reconsider this; it is possible that plasma from vaccinated individuals may offer a life-saving supplement to treatment in individuals diagnosed late in the course of a fulminating anthrax infection. Interestingly, antianthrax (horse) serum is still administered together with penicillin in the treatment of human anthrax in China.

Infections by *Bacillus* species other than *B. anthracis* are too infrequent and varied to merit development of any vaccines; consequently the topic of immunity in relation to such infections is an area that has not been studied.

BACTERIA, IMMUNITY TO

Graham AW Rook, Department of Bacteriology, University College London Medical School, London, UK

Bacteria cause disease because of toxicity, invasiveness, immunopathology, or blends of these three mechanisms. Thus much of the interaction between a given bacterial species and the immune response can be predicted by considering the immunological mechanisms available in relation to the mechanism of pathogenicity, and the structure of the bacterium. For a toxigenic bacterium, neutralizing antibody may be all that is needed. Otherwise destruction of the organism itself may be required.

Nonspecific defenses

Nonspecific recognition of common bacterial structures

Much of the defense against bacteria depends on pathways which have nothing to do with the specific antigen receptors of either B cells or T cells, and

probably antedate these in evolution. Many bacteria are simply excluded by barriers such as skin, acidity in gut and vagina, commensals occupying the relevant niche, entrapment by mucus, etc. If not excluded, the organism may be recognized by:

1. Acute phase proteins, C-reactive protein and mannose-binding protein which also fix complement.
2. Receptors for the formyl peptides released by bacteria which are chemoattractants and activators of phagocytes.
3. Receptors for bacterial cell wall components, glycolipids, glucans and other polysaccharides that nonspecifically enhance the immune response, and can be used as immunological adjuvants.
4. Complement, activated in the absence of antibody by a wide range of bacterial components.

5. Receptors that lead to cytokine release. The bacterial products which do this include endotoxin (lipopolysaccharide, LPS) of gram-negative organisms, lipoteichoic acids of gram-positive cocci, and the lipoarabinomannan of mycobacteria. It is probable that all bacteria contain cytokine triggers.

Nonspecific recognition and selection of response mechanism Collectively these nonspecific recognition pathways perform crucial functions. First, the pattern of nonspecific recognition events, cytokines and bacterial products supplies information as to the type of immune response that needs to be activated. This immunoregulatory 'decision' is particularly important because activation of inappropriate effector mechanisms can lead to enhanced susceptibility rather than to protection. These features account for the 'adjuvant' properties of bacterial components, which are often used by immunologists to boost or direct responses to other antigens. For example, the adjuvant properties of *Bordetella pertussis* and *Mycobacterium tuberculosis* impose different balances of T_H1 to T_H2 cytokines on the T cell response to any simultaneously administered antigen. If the immune system activates a T_H2 pattern of response to a mycobacterial pathogen, accelerated disease will result.

Other factors influencing the T_H1/T_H2 balance of the T cell response Dose and the different handling of soluble versus particulate antigen are also important. Low dose soluble antigen selectively primes T_H2 , while low dose particulate antigen selectively primes T_H1 . These relationships reverse as dose is increased. The reason appears to be that presentation of low dose soluble antigen is mostly by B cells, which tend to drive T_H2 , while presentation of low dose particulate antigen (such as bacteria, or *Leishmania*) is mostly by macrophages, which tend to drive T_H1 .

Local metabolism within lymph nodes of glucocorticoids (cortisol), and of dehydroepiandrosterone (which yields metabolites that oppose some effects of cortisol), also profoundly influences T_H1/T_H2 cytokine balance. Cortisol diverts the response to T_H2 , and is partly responsible for increased susceptibility to certain infections in stressed individuals.

Nonspecific recognition and early defense: the protective role of cytokines The nonspecific recognition events cause sufficient activation of the immune system to mobilize a 'holding operation' that can control bacterial growth while specific immunity develops. The cytokines released have

rapid protective effects, but if their release is excessive or prolonged, they can cause severe immunopathology, and even death (see below). Nevertheless tumor necrosis factor α (TNF α) protects mice from *M. avium*, *Legionella pneumophila*, *Streptococcus pneumoniae* and *Klebsiella*. The mechanisms of protection by cytokines, particularly TNF α , include rapid induction (<5 min) of increased adhesion of neutrophils to endothelial cells, increased expression of CR3 and other cell adhesion molecules, priming of neutrophils for enhanced production of oxygen reduction products, and activation of macrophages. Cytokines also affect 'nonprofessional' phagocytes, and exposure of Hep-2 cells (derived from a human carcinoma of the larynx) to TNF α renders them resistant to invasion by *Salmonella typhimurium*. Similarly, interferon γ (IFN γ) derived from natural killer (NK) cells will activate killing mechanisms in macrophages.

Interactions of bacteria with complement Numerous bacterial components can activate the alternative pathway. This results in three categories of protective function:

1. Release of the chemotactic products. C3a and C5a. These cause smooth muscle contraction, mast cell degranulation, and neutrophil chemotaxis and activation.
2. Attachment to the organism of derivatives of C3, which play an important role in the subsequent interaction with phagocytes.
3. Killing of some gram-negative organisms if the lytic complex C5b-C9 gains access to the outer lipid bilayer.

Many organisms have devised strategies to resist these effects of complement. Some capsules are very poor activators of the alternative pathway. Alternatively, long side-chains (O antigens) on LPS may fix C3b at a distance from the vulnerable lipid bilayer. Similarly, smooth gram-negative organisms (*Escherichia coli*, *Salmonella*, *Pseudomonas*) may fix but then rapidly shed the C5b-C9 membrane complex. Capsules rich in sialic acid (like host cell membranes) promote the inactivation of C3b by interaction with factors H and I, and *Neisseria meningitidis*, *E. coli* K1 and group B streptococci resist complement attachment in this way. The M protein of group A streptococci acts as an acceptor for factor H and there is a gene for a C5a protease close to the M protein gene.

Role of antibody

Antibody clearly plays a crucial role during infections with toxigenic organisms. It neutralizes diphtheria toxin by blocking the attachment of the binding portion of the molecule to its target cells. Similarly it may block locally acting toxins, extracellular matrix-degrading enzymes which act as spreading factors, and motility due to flagella. An important function on external surfaces, often performed by secretory immunoglobulin A (IgA), is inhibition of binding of bacteria to epithelial cells. It is also likely that some antibodies to the bacterial surface can block functional requirements of the organism such as receptors for iron-chelating compounds or the intake of nutrients. However, the most important role of antibody in immunity to nontoxigenic bacteria is the more efficient targeting of complement so that even organisms that resist the alternative pathway by the mechanisms described in the previous section are damaged by complement, or become coated with C3 products.

Interactions between bacteria and phagocytic cells

The important consequence of the inflammatory and chemotactic events triggered by bacteria in the tissues is the enhanced exposure of the bacteria to phagocytic cells.

Binding, uptake and the triggering of killing

The first stage in the intracellular killing is the attachment of the organism to the surface of the phagocyte. This important and complex interaction determines whether uptake occurs, and whether killing mechanisms are triggered. In addition to complement and antibody, this interaction can involve C-reactive protein, lectins on the organisms and on host cell membranes, the family of adhesion-promoting receptors CR3, LFA-1, p150,95 and the integrins. Some organisms are able to enter cells via unconventional receptors, such as integrins, and so avoid triggering killing mechanisms.

Antimicrobial mechanisms of phagocytic cells

Activation of antimicrobial functions

Monocytes and polymorphonuclear cells possess a number of oxygen-dependent and oxygen-independent antimicrobial mechanisms. These, while often constitutively expressed, can be activated directly by bacterial products or by cytokines such as IFN γ .

Oxygen-dependent pathways: derivatives of superoxide anion Oxygen is reduced by a membrane-associated cytochrome system which transfers an electron onto molecular oxygen to form superoxide anion ($O_2^{\cdot -}$), usually during phagocytosis. Subsequent interactions give rise to hydrogen peroxide (H_2O_2), hydroxyl radicals ($\cdot OH$), and perhaps singlet oxygen (Δ^1O_2), which is oxygen with one electron in a high energy state. These toxic intermediates are generated in the absence of myeloperoxidase (MPO) and therefore do not require fusion of the MPO-containing lysosomes with the phagosome. If fusion does occur, MPO catalyzes the formation of hypohalous acids from H_2O_2 and halides.

Oxygen-dependent pathways: nitric oxide Nitric oxide (NO) is formed from the guanidino nitrogen of L-arginine, by NO synthase, yielding citrulline as the other product. Formation of NO is enhanced by exposure to IFN γ and a trigger of TNF α release such as endotoxin, or the equivalent cytokine triggers of other organisms. The NO is a relaxant of vascular smooth muscle and has poorly understood roles in intracellular signaling. Within macrophages it probably acts as an antimicrobial agent, though such effects are difficult to distinguish from its signaling role. Whatever the mechanism, agents that block NO synthase enhance growth of *M. tuberculosis* within macrophages both *in vivo* and *in vitro*. It is more difficult to make human macrophages generate high levels of NO, but it is now clear that they can do if stimulated with mixtures of cytokines (interleukin 4 (IL-4) and IFN γ) or further triggered by cross-linking CD23.

Oxygen-independent pathways

Some oxygen-independent killing may be due to the sequential exposure to lysozyme and neutral proteases at pH 7.0–8.0, followed by acid hydrolases after the acidification step, but several more specific pathways have now been defined.

Cationic proteins Human granulocytes contain cationic proteins with microbicidal activity. Six have been sequenced and are cysteine- and arginine-rich peptides of 32–34 amino acids with molecular weights of about 4 kDa. They are representatives of a conserved family of related mammalian ‘antibiotics’ which have been named ‘defensins’. Similar proteins are found in the granules of rabbit alveolar macrophages but not in human macrophages, although these contain other cationic antibacterial substances, some of which are enzymes, which kill gram-positive and -negative bacteria and fungi by mechanisms quite independent of their enzymatic activity. More-

over, it is likely that the uptake of enzymes and cations from other cells plays a significant role in macrophage antibacterial function *in vivo*. The defensins will kill organisms as diverse as *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *E. coli*, *Cryptococcus neoformans* and even the enveloped virus, *Herpes simplex*.

Tryptophan deprivation Exposure to IFN γ causes degradation of tryptophan in monocytes and fibroblasts. This amino acid is essential for some pathogens.

Cell-mediated immunity

This term is usually reserved for immunity that involves direct intervention of T lymphocytes. One of their functions is the release of lymphokines, which has several types of consequence.

1. Lymphokines attract monocytes and polymorphonuclear cells to the site of infection.
2. Lymphokines enhance antimicrobial functions of phagocytic cells. The major lymphokine for these functions is IFN γ .
3. It is likely that the mechanisms described in 1) and 2) constitute the basis for the delayed hypersensitivity reaction to skin-test challenge with soluble antigen, typified by the Mantoux test.
4. When release of lymphokines and accumulation of mononuclear cells is persistent, the characteristic T cell-dependent tuberculoid granulomas are formed. These granulomas can be isolated and the release of cytokines monitored *in vitro*. *In vivo* TNF α also seems to be involved and neutralizing antibodies to TNF α will block granuloma formation in response to BCG. It is likely that granulomas serve to isolate organisms within a focus of activated macrophages.
5. IFN γ also evokes antimicrobial mechanisms in other cells, such as endothelial cells which are incapable of the oxidative burst, as shown with *Rickettsia* and *Chlamydia psittaci*. Many cell types are capable of activation to produce nitric oxide.

Cytotoxic T cells

Cytotoxic T cells are also generated during the cell-mediated response to intracellular pathogens. These can kill infected or antigen-pulsed macrophages. It is becoming apparent that this phenomenon is at least as important as macrophage activation and may serve to release bacteria from macrophages that are failing to kill ingested bacteria and are merely acting as sites for intracellular growth. Following the death

of such cells, the bacteria can be taken up by fresh activated phagocytes.

Until recently the term 'cytotoxic T cell' was almost synonymous with CD8⁺ T cells with α/β receptors, recognizing peptide epitopes presented by major histocompatibility complex (MHC) class I. Now several other T cell types are known to be potentially cytotoxic, including some CD4⁺ cells.

γ/δ T cells In the mouse, mycobacterial infection leads to a disproportionate increase in the γ/δ T cell receptor-bearing population. Moreover γ/δ T cells which respond to mycobacterial antigens can be isolated from the lesions of some types of leprosy, and a strikingly high percentage of the circulating γ/δ T cells from normal donors respond to *M. tuberculosis*. Among the antigens recognized by these cells are heat shock proteins, compounds containing 5'-triphosphorylated thymidine, and phenyl pyrophosphate derivatives. They are cytotoxic and usually IFN γ secreting.

CD4⁻CD8⁻ CD1-restricted α/β T cells These T cells recognize antigens presented by CD1, which is a remotely MHC class I-like membrane glycoprotein. Clones have been identified that respond to mycobacterial glycolipids and lipids, so like γ/δ cells they indicate that recognition of bacteria by T cells does not depend only on recognition of peptide epitopes.

NK cells These lymphocytes kill cells that fail to express self MHC class I. There is unconfirmed evidence that some NK cells can directly damage certain bacteria. NK cells also play a role in macrophage activation through release of IFN γ . This pathway may provide the source of IFN γ in severe combined immunodeficiency (SCID) mice, which are unexpectedly resistant to many infections.

Avoidance of antimicrobial mechanisms of phagocytic cells

Organisms may secrete toxins which repel or kill the phagocytes. Capsules of carbohydrate (*Str. pneumoniae*) or polypeptide (*Bacillus anthracis*) may impede complement deposition and phagocytosis. The M proteins of group A streptococci limit uptake by phagocytes, while permitting specific attachment to the epithelium of the oropharynx. Other organisms are taken up, but fail to trigger the oxidative burst. Secretion of polyanions or ammonia have been reported to block phagolysosome fusion, although the methods used to demonstrate these phenomena have recently been re-evaluated. Superoxide dismutase and catalase can degrade oxygen intermediates,

and the phenolic glycolipid secreted by *M. leprae* may act as a scavenger of oxygen radicals. The lipoarabinomannan released from mycobacteria may inhibit lymphokine-mediated macrophage activation, as murine macrophages heavily infected with *M. leprae* cannot be activated to kill a protozoan. Other organisms avoid antimicrobial mechanisms by escaping from the phagosome. *M. leprae* and *Shigella flexneri* can multiply free in the cytoplasm, while *Brucella abortus* and *Legionella pneumophila* are found in the rough endoplasmic reticulum.

It is increasingly apparent that many bacteria, like viruses, hijack cellular machinery for their own use. *Listeria monocytogenes* uses 'hemolysins' to lyse the phagosome, and then interacts with actin in the cell in order to propel itself towards and into neighbouring cells. Finally, some organisms, such as *M. tuberculosis* tend to kill the macrophage, perhaps by rendering them sensitive to the TNF α which they themselves are induced to release.

Mechanisms of immunopathology

Septicemic shock and the adult respiratory distress syndrome

The cytokine release triggered by bacterial components has a protective and immunoregulatory role as described above, but when excessive, as during septicemia, there can be excessive systemic activation of phagocytes and of endothelial cells. The latter leads to adhesion of phagocytes to the endothelium, initiation of the clotting cascade via expression of tissue thromboplastin, and eventually to diffuse intravascular coagulation that exhausts the clotting system and leads to a clotting defect. Mediators such as platelet-activating factor (PAF) and NO are released, blood pressure falls and hemorrhage may occur. Neutralizing antibodies to tissue thromboplastin or inhibitors of PAF can attenuate this syndrome. A neutralizing antibody to TNF α is protective in a model of septicemic shock in the baboon. The systemic toxicity of TNF α is greatly increased in the presence of IL-1 or LPS and these are both likely to be present during bacterial infections. High serum levels of TNF α correlate with a poor clinical outcome in septicemia, and in the adult respiratory distress syndrome (ARDS), which is a similar condition that targets the lungs.

Shwartzman reaction

Cytokine release can also cause local rather than systemic pathology. Microbial products and certain types of inflammatory response (both T cell dependent and independent) 'prepare' tissue sites so that

they become exquisitely sensitive to cytokines, particularly TNF α , and liable to undergo hemorrhagic necrosis if TNF α release is subsequently induced systemically, or if TNF α is directly injected into the same site. This may explain the rash often seen during meningococcal septicemia. If bacteria released during a previous subclinical septicemic episode have lodged in skin capillaries, these will become 'prepared' sites, and a later septicemic episode severe enough to trigger systemic cytokine release will cause these sites to undergo necrosis via a cascade of events similar to those occurring systemically in endotoxin shock.

Koch phenomenon and necrotizing T cell-dependent granulomas

Robert Koch observed that when tuberculous guinea pigs were skin-tested with tuberculosis bacilli or culture supernatant (tuberculin), there was a necrotic reaction at the skin-test site within 24–48 h, and if a large dose of tuberculin was used there was additional necrosis in distant tuberculous lesions. The same is true in human tuberculosis patients. This phenomenon is described in the section on mycobacteria, and probably represents a pattern of tissue destruction and eventual fibrosis that occurs when there is local release of TNF α and other cytokines into T cell-dependent inflammatory sites mediated by a mixed T_H1 plus T_H2 lymphocyte response. A similar argument holds for tissue damage around granulomas evoked by schistosome ova, so the Koch phenomenon may be a model of an important immunopathological entity.

Heat shock proteins and the possibility of autoimmunity

It was discovered recently that several dominant antigens of infectious agents are 'heat shock' or 'stress' proteins. The sequences of these microbial antigens are similar to the sequences of the mammalian homologs. The fact that the immune response focuses much 'attention' on these conserved proteins may increase the chances of recognizing any pathogen, but also increase the chance of autoimmunity.

BACTERIAL CELL WALLS

Alan Cockayne, Department of Microbiology, University of Nottingham, Nottingham, UK

The bacterial cell wall is a rigid, complex macromolecular structure which surrounds the bacterial cytosol and determines the characteristic shape of different bacteria. The cell wall and associated membrane(s), often referred to as the cell envelope, in addition to maintenance of cell shape, perform several important physiological functions involved in the regulation of interactions between the organism and its environment. In particular, the bacterial surface is the site of interaction of the organism with host tissues, and the molecular architecture of the cell envelope is of key importance in the pathogenesis of bacterial infection. Some components act as receptors or adhesins and mediate attachment to host cell surfaces. Many cell envelope components are anti-

genic and stimulate host immune responses which may be important in controlling or eradicating infection. In contrast, other components inhibit immune interactions and contribute both to the initiation of infection and persistence of the organism in host tissues. Expression of many envelope components is influenced by environmental conditions. Products expressed under conditions which most closely mimic those found *in vivo* are of increasing interest in understanding the pathogenesis of bacterial infections.

The majority of bacteria can be classified into one of two types, gram-positive or gram-negative, using a simple staining technique which exploits fundamental differences in the structure of the cell envelope.

ope to differentiate between the two groups. The principal components of the cell envelopes of gram-positive and gram-negative bacteria are shown in Figure 1.

Cytoplasmic membrane

This bounds the bacterial cytoplasm. Proteins present in the membrane are involved in selective transport of nutrients and synthesis of peptidoglycan and periplasmic and outer membrane proteins. In gram-negative organisms, the space between the cytoplasmic membrane and the outer membrane – the periplasmic space – contains proteins with catabolic, binding and degradative functions.

Peptidoglycan

This is the major component of the cell wall involved in maintenance of cell rigidity, shape and osmotic stability and may be referred to as murein or mucopeptide. It consists of a polymer of $\beta 1 \rightarrow 4$ -linked *N*-acetylmuramic acid and *N*-acetyl-D-glucosamine residues which are cross-linked by peptide bridges. The antibiotic penicillin interferes with peptidoglycan synthesis by inhibiting peptide bridge forma-

tion. Peptidoglycan is present in all bacteria except mycoplasmas and some halophilic archaeobacteria. In gram-negative bacteria the peptidoglycan layer may be only one or two molecules thick but in gram-positive bacteria it is much thicker. Removal of the peptidoglycan by treatment of bacteria with lysozyme generates osmotically fragile structures termed protoplasts in gram-negative bacteria and spheroplasts in gram-positive organisms; L-forms are bacterial variants that have lost the ability to synthesize peptidoglycan. Peptidoglycans of many bacteria are antigenic, and a degradation product of mycobacterial peptidoglycan – muramyl dipeptide (MDP) – has adjuvant properties.

Gram-negative outer membrane

In gram-negative bacteria such as *Escherichia coli*, the peptidoglycan layer is surrounded by a second bilayer lipid membrane, the outer membrane. The outer membrane is linked to the peptidoglycan layer by a lipoprotein and contains proteins and a highly immunoreactive molecule called lipopolysaccharide (LPS) or endotoxin.

Some outer membrane proteins (OMPs) function as receptors or ligands, and one group – the porins –

Figure 1 Components of the cell envelope of gram-positive and gram-negative bacteria. *Not always present.

form transmembrane channels involved in the non-specific transport of small hydrophilic solutes across the membrane. Other proteins mediate specific uptake of larger metabolites. Expression of some OMPs is regulated by environmental factors, such as growth medium composition. For example, many gram-negative bacteria express iron-regulated OMPs when growing in iron-deficient media. *In vivo* such proteins are involved in scavenging iron in mammalian tissues, a prerequisite for bacterial growth, and are therefore important virulence determinants of bacterial pathogens. Many OMPs are antigenic, and antigenic variation in these proteins is important in the pathogenesis of diseases such as gonorrhea (caused by *Neisseria gonorrhoeae*) and relapsing fever (caused by *Borrelia* spp.). Some OMPs contain T cell epitopes and stimulate cell-mediated responses which may modulate the immune response during infection. OMPs are also involved in the resistance of some intracellular bacteria to the bactericidal effects of phagocytic cells.

LPS or endotoxin is a complex molecule present in the outer leaflet of the outer membrane. It contains a unique lipid moiety – lipid A – which is responsible for its diverse biological activities including pyrogenicity and activation of macrophages. Many of its effects are nonspecific and are mediated through cytokines such as tumor necrosis factor α (TNF α) and interleukin-1 (IL-1) produced following interaction of LPS with lymphocytes or macrophages. LPS also contains oligosaccharides that confer antigenic specificity on the molecule and constitute the ‘O’ or somatic antigens of gram-negative bacteria such as *Salmonella*. The oligosaccharide side-chains are also important in preventing access of activated complement components to the bacterial outer membrane. Recent studies have shown that LPS of some bacteria, e.g. *Helicobacter pylori*, contain sugar sequences identical to human blood group antigens, which may play a role in modulating the immune response to the bacterium. The LPS of some bacteria, e.g. *Neisseria* spp., naturally lacks the oligosaccharide side-chains and these molecules are referred to as lipo-oligosaccharides (LOS).

Other components of gram-positive cell envelopes

Gram-positive bacteria lack an outer membrane but proteins, lipoproteins and other macromolecules are associated with the cytoplasmic membrane and peptidoglycan. Many wall proteins are anchored directly to the peptidoglycan, and contain a conserved amino acid motif – LPXTG – which is involved in transporting these proteins across the cytoplasmic mem-

brane. Lipoproteins, which may be highly immunogenic, are anchored to the cytoplasmic membrane by the N-terminus which is lipid modified. Expression of both wall and cytoplasmic membrane proteins may be influenced by environmental factors such as iron availability. Also associated with the surface of some gram-positive bacteria are immunoglobulin-binding proteins such as staphylococcal protein A and streptococcal protein G, which bind the Fc region of antibody molecules. Proteins with analogous function are now being detected in some gram-negative bacteria. Release of such proteins may protect the organism by binding to antibody and preventing its deposition on the bacterial surface. Other proteins such as the M protein of *Streptococcus pyogenes* have an antiphagocytic function.

Teichoic and lipoteichoic acids are acidic polymers of glycerol or ribitol and are bound to the peptidoglycan and cytoplasmic membrane respectively. They may be important antigens in staphylococci and streptococci, stimulating both humoral and cell-mediated immune responses.

Bacterial capsules

The outermost layer of many bacteria consists of a capsule. Capsules are usually, but not exclusively, acidic polysaccharides and are only loosely associated with the bacterial surface. Capsules may act as adhesins or have antiphagocytic functions due to their acidity and hydrophilic nature. In addition, capsular material may be poor antigenic (e.g. the hyaluronic acid capsule of *Streptococcus pyogenes*) and may mask more antigenic deeper layers of the cell envelope. The presence of a capsule may also sterically hinder access of complement components to the bacterial outer membrane. Other capsular antigens induce opsonizing antibody which promotes clearance of the bacteria. Although successful vaccines based on conjugated capsular polysaccharides have been developed, e.g. *Haemophilus influenzae* serotype b, some bacteria, e.g. *Streptococcus pneumoniae*, produce more than 30 antigenically distinct capsular types, which makes development of cross-protective capsular vaccines very difficult.

Other components associated with the bacterial cell envelope

Also associated with the surface of many gram-negative bacteria and some gram-positive organisms are filamentous appendages called pili or fimbriae. These are proteinaceous and are involved in mediating specific attachment of some bacteria to cell

surfaces. Antigenic variation in pili may also be important in the pathogenesis of gonorrhea.

In both gram-positive and gram-negative bacteria, flagella – organelles involved in motility – are anchored into the cell envelope. Flagella are antigenic and constitute the 'H' antigens of gram-negative bacteria.

Mycobacteria do not readily stain by Gram's method and have a cell envelope which is unusually rich in lipids. This property confers the property of 'acid fastness' on these organisms since they resist decolorization with acids following staining. The lipid component of mycobacteria probably contributes to their resistance to phagocytic killing and the difficulty encountered in their degradation by these cells. Included among the lipids are mycolic acids or cord factors which may be toxic for mammalian cells.

BACTERIAL IMMUNOGLOBULIN-BINDING PROTEINS

Michael DP Boyle, Medical College of Ohio, Department of Microbiology and Immunology, Toledo, Ohio, USA

Bacterial immunoglobulin-binding proteins represent a family of functional molecules expressed by certain microorganisms that can interact with immunoglobulins (Igs) at sites unrelated to their antigen-combining regions. The study of these molecules was initially driven by their utility as immunochemical reagents but has now expanded to address more basic scientific questions of structure–function and biological activities.

Six types of IgG-binding proteins have been described on gram-positive bacteria. These different types have been classified by their ability to bind with the Fc region of different mammalian species and subclasses of IgG (Figure 1). The most extensively studied IgG-binding protein is protein A (the type I).

Protein A is expressed by the majority of human isolates of *Staphylococcus aureus*. The type II receptors are found on the surface of the majority of human isolates of group A streptococci and display a large amount of variability in their immunoglobulin-binding profiles (Table 1). Protein G, the type III IgG-binding protein, is expressed by the majority of human group C and G streptococcal isolates and displays the widest range of species and subclass reactivities of any of the immunoglobulin-binding proteins identified to date (Figure 1). The type IV, V and type VI immunoglobulin-binding proteins are associated with animal isolates of streptococci and have not been studied extensively.

Figure 1 Profile of species reactivities of different bacterial IgG-binding protein types. Larger dots represent greater binding activity; o, no reactivity; nt, not tested. Note these reactivities have been determined using polyclonal IgG preparations. Occasional differences have been noted in the reactivity of samples from individual animals. (Reproduced with permission from Reis *et al* (1988).)

IgG Fc-binding proteins have also been described on the surface of other bacteria, including *Haemophilus somnus*, *Clostridium perfringens*, *Brucella abortus*, *Taylorella equigenitalis* and *Gardnerella vaginalis*. In addition, bacterial binding proteins that display nonimmune reactivity with immunoglobulin isotypes other than IgG have been described (Table 2). These include proteins that bind constant regions in IgD or IgA. Other proteins have been recognized that bind regions within constant portions of the

F(ab)'₂ fragments as well as molecules that show selective reactivity with immunoglobulin light chains. To date, a bacterial protein with absolute selectivity for the Fc region of IgM from any species has not been described. A *B. abortus* protein with reactivity for certain bovine IgM allotypes, a *Clostridium difficile* toxin protein that displays preferential reactivity with murine IgM, and a potential IgM-specific lectin-like molecule of *Borrelia burgdorferi* have been reported.

Table 2 Representative bacteria that bind immunoglobulin in a nonimmune fashion

Bacteria	IgG	IgM	IgA	IgD	IgE

<i>Peptococcus magnus</i>	+	+	+	+	+
<i>Haemophilus somnus</i>	+				

*Reactivity limited to a subgroup of bovine IgM antibodies.

Protein A – the type I IgG-binding protein

The initial IgG-binding protein described and characterized was the type I binding protein expressed on the surface of the majority of *Staphylococcus aureus* isolates and more frequently designated as staphylococcal protein A. Protein A and its interaction with the Fc region of reactive IgG antibodies has been extensively studied and detailed structure–function analysis by X-ray crystallography and nuclear magnetic resonance has mapped the key binding amino acids in the selective interaction of protein A with the C_{H2}–C_{H3} domain of IgG.

The interaction of protein A and IgG is of relatively high affinity 10^8 – 10^9 M⁻¹ and a lower affinity interaction has also been noted for protein A binding to F(ab)₂ regions of IgG. In addition, reactivity of protein A with certain subtypes of IgM and IgA have also been described. The gene encoding protein A has been cloned and contains four or five homologous regions capable of binding to IgG.

Protein A is bivalent in its IgG-binding activity and in the presence of excess IgG forms (IgG)₂ (PA) complexes. When protein A is present in excess the predominant complex is (IgG)₁ (PA)₂, indicating the presence of two protein A binding domains on each IgG molecule. These different protein A–IgG complexes display different potentials for binding C1 and activating the classical complement pathway. The (IgG)₁ (PA)₂ complexes do not bind C1 indicating, that protein A and C1q target a similar site on the Fc region of IgG, whereas a dimer of the [(IgG)₂ (PA)₁]₂ complex is extremely efficient in binding and activating C1 and behaves in complement fixation assays with the characteristics of an IgM antibody. The ability to form such IgM-like complexes may explain the ability of protein A to induce wheal and flare reactions when injected into humans intradermally or to induce anaphylactic reactions in guinea pigs.

In addition to effects of protein A on the humoral immune system, the bacterial protein has also been reported to have T cell mitogenic properties and to act as a B cell superantigen. The T cell effects of protein A, however, are based on earlier studies of responses induced by heat-killed and/or formalin-fixed *S. aureus* Cowan strain bacteria or wild-type preparations of protein A. These sources of protein A have the potential to be contaminated with staphylococcal enterotoxins, which could account for many of the observed effects. Studies with recombinant protein A, which demonstrates all of the expected IgG-binding activities, failed to show T cell mitogenic activity, suggesting protein A may not be a T cell mitogen. By contrast, the elegant studies of Silverman and colleagues indicate that protein A can induce proliferation of a subset of human B cells and this is restricted to B cells expressing surface immunoglobulin containing certain V_{H3} Fab regions.

The majority of studies of protein A have focused on its utility as a reagent for detection of antigen–antibody complexes or, once immobilized, as a reagent for affinity purification. The high selectivity of protein A for the Fc region of antibodies in immune complexes has resulted in protein A tracers replacing conventional second antibody reagents in many immunotechnological applications. Protein A has proved to be extremely valuable for procedures involving screening of hybridoma supernatants for a desired monoclonal antibody with a desired specificity as well as for the subsequent purification of that antibody.

Analysis of the infectivity of *S. aureus* isolates and paired mutants in which the protein A gene was non-functional have failed to provide any evidence that protein A is a virulence factor.

Type II IgG-binding proteins

Group A streptococci express an array of functionally distinct IgG-binding proteins (Table 1). The majority of the functional types of type II IgG-binding proteins have been cloned and sequenced. All of these IgG-binding proteins are encoded by M or M-related protein genes that are present in a virulence regulon of group A streptococci, suggesting a potential role for these proteins in pathogenesis. In addition to binding IgG, the majority of type II binding proteins also bind other plasma proteins, e.g. albumin, factor H, fibrinogen, plasminogen and IgA. Analysis of the binding domains of these proteins suggest they consist of different combinations of distinct functional modules that react with different IgG subclasses or other plasma proteins. Expression of type II IgG-binding proteins is associated more frequently with group A streptococcal skin isolates than with throat isolates. Studies in mice have indicated an association between IgG-binding protein expression and skin infectivity, while no such association occurs when the bacteria are injected intraperitoneally.

Type III IgG-binding proteins

The type III IgG-binding proteins are more frequently designated as streptococcal protein G. Protein G is expressed by the majority of human isolates of group C and group G streptococci. A number of variant forms of protein G have been described at both the gene and protein level. All forms of protein G are antigenically related and the majority also bind human serum albumin. The gene encoding protein G has been cloned and the albumin-binding and IgG-binding domains have been shown to be distinct. This has enabled nonalbumin-binding forms of protein G to be genetically engineered.

Protein G demonstrates the widest species and subclass reactivity of any bacterial IgG-binding protein (Figure 1). Protein G, like protein A, can form a number of different-sized complexes with IgG and these demonstrate a similar pattern of complement-fixing potential to that observed with protein A. Protein G has been shown to mediate mitogenic responses when added to human peripheral blood lymphocytes. This activity, however, could not be correlated with either the albumin or IgG-binding domain of the protein.

By virtue of its broad species and subclass reactivity profile, protein G is an extremely useful reagent as a tracer and for affinity purification of antibodies that are not reactive with protein A.

Type IV, V and VI IgG-binding proteins

Type IV, V and VI IgG-binding proteins have not been extensively studied. They are all antigenically distinct proteins that demonstrate different patterns of nonimmune IgG binding (Figure 1). The type IV binding protein is associated with certain β hemolytic isolates of streptococci from cattle; however, this protein demonstrates no detectable reactivity with bovine immunoglobulins. The type V and VI proteins have been isolated from different *S. zooepidemicus* isolates. It is probable that, like type II IgG-binding proteins, there will be extensive heterogeneity in the IgG-binding proteins expressed by different *S. zooepidemicus* isolates. To date, there is no evidence that any type IV, V or VI IgG-binding protein associates with disease in any animal species and none of these proteins have been tested for their utility as immunochemical reagents.

Other bacterial immunoglobulin-binding proteins

In addition to the IgG-binding proteins associated with staphylococci and streptococci, an increasing number of both gram-positive and gram-negative bacteria have been reported to express immunoglobulin-binding proteins with reactivity for IgA, IgD and IgM, as well as a protein that binds to certain κ light chains (Table 2). To date, no disease association has been suggested for any of the putative IgA-, IgM- and IgD-binding proteins. The Fc binding protein associated with *H. somnus* has been implicated as a virulence factor in cattle and an association between expression of protein L, a light chain-binding protein, by *Peptococcus magnus* and vaginal infections has been proposed.

As might be anticipated, based on the utility of protein A and protein G, many of these immunoglobulin-binding proteins may find applications for the purification and detection of specific immunoglobulin classes or subclasses. To date, the light chain-binding protein (protein L), a hybrid of protein L and protein G (LG), and a group B streptococcal IgA-binding protein (protein B) have demonstrated practical utility in certain immunological procedures.

Summary

Immunoglobulin-binding proteins represent a family of diverse molecules capable of interacting with antibody without impairing the ability of the antibody to bind its cognate antigen. By virtue of these properties, these molecules are potentially valuable

immunochemical reagents. There is limited understanding of the role of IgG-binding proteins in bacterial virulence. Studies of *H. somnus* in cattle and *S. pyogenes* and *Peptococcus magnus* in humans have suggested a possible association between expression of IgG-binding proteins and the course of infection.

BACTEROIDES, INFECTION AND IMMUNITY

Michael E Shapiro, Harvard Medical School, Beth Israel Hospital, Boston, Massachusetts, USA

The importance of anaerobic bacteria in clinical human disease, particularly intra-abdominal infection, has been well established over the past two decades. Much of the interest has focused upon the various *Bacteroides* species because of their prevalence in clinical isolates and their requirements for particular antibiotic therapy. Once classified as subspecies of *Bacteroides fragilis*, six distinct species of *Bacteroides* are now recognized based on distinctive patterns of DNA homology: *B. fragilis*, *B. distasonis*, *B. vulgatus*, *B. thetaiotaomicron*, *B. ovatus*, and *Bacteroides* species. Although *B. vulgatus* and *B. thetaiotaomicron* are the numerically dominant species of the fecal flora, *B. fragilis*, a numerically minor member of the normal flora, is the most frequently isolated anaerobic species in many infectious processes, including intra-abdominal sepsis. This sug-

gests that *B. fragilis* must possess virulence factors not present in the other species.

Examination of clinical isolates of *B. fragilis* has demonstrated the presence of a polysaccharide capsule, rarely found on other *Bacteroides* species. The capsular polysaccharide of *B. fragilis* has been well characterized chemically. Prolonged laboratory culture of encapsulated strains of *B. fragilis* may result in loss of the capsule and a marked diminution in virulence.

Much of our knowledge about *Bacteroides* virulence comes from a rat model of intra-abdominal sepsis, in which bacterial isolates are placed in a gelatin capsule along with adjuvants and implanted intraperitoneally. Using complex mixtures of fecal flora, an early peritonitis phase, with bacteremia and high mortality, is followed by an abscess phase. This

latter phase has been shown to be dependent upon the presence of anaerobes in the inoculum. When various isolates were tested in this model, it was shown that encapsulated strains of *B. fragilis* were the only organisms capable of abscess formation as single isolates. Unencapsulated strains of *B. fragilis* and other anaerobes only led to abscess formation when combined with other facultative organisms, such as enterococcus. In fact, heat-killed preparations of encapsulated *B. fragilis* strains led to abscess formation in the majority of cases, as did inocula containing purified capsular polysaccharide, clearly demonstrating the role of the capsule in virulence.

The apparent central role of capsular polysaccharide in *B. fragilis* virulence led to studies using the polysaccharide as a vaccine. Rats immunized with *B. fragilis* capsular polysaccharide with or without complete Freund's adjuvant developed significant antibody titers against the polysaccharide. These animals were protected against abscess formation when challenged with *B. fragilis* or *B. distasonis*. Animals challenged with more complex bacterial inocula still formed abscesses; however, *B. fragilis* was eliminated from the abscesses in those animals. Surprisingly, when serum from immunized animals with high-titer antibody to the capsular polysaccharide was transferred to nonimmunized animals, no protection against abscess formation was conferred. On the other hand, transfer of spleen cells from immunized animals did confer protection and this result could be repeated with spleen cells enriched for T cells with nylon-wool columns. Similarly, immunization of athymic nude rats with capsular polysaccharide, although producing excellent antibody levels, did not prevent abscess formation whereas phenotypically normal littermates were protected. Thus, in the rat model, there was a strong suggestion for the role of T cell immunity in the immune response to *B. fragilis* and abscess prevention.

A murine model of intra-abdominal abscess formation was developed in order to better dissect the cellular immune response to *B. fragilis*. This model has the further advantage that the bacterial inoculum can be introduced without surgical implantation. It was possible to confirm all of the rat observations in the murine system, namely, that immunization with capsular polysaccharide was protective against *B. fragilis* abscesses, that protection could not be transferred passively with serum, but could be conferred by spleen cell transfers. The cell responsible for protection was, in fact, a T cell, of the $\text{Ly-1}^- \text{Ly-2}^+ \text{I-J}^+$ phenotype. The immune T cells are antigen specific, that is, they only protect against *B. fragilis* abscesses, but are not major histocompat-

ibility complex (MHC)-restricted. This immune T cell produces a factor and transfer of cell-free lysate of immune T cells are protective against abscesses as well. The factor is polypeptide in nature and of relatively low molecular weight (<12 kDa).

Because of the immune T cell phenotype and the elaboration of a soluble factor, the possibility that abscess prevention might be mediated by a T cell suppressor circuit was raised. This possibility raised two questions: what was being suppressed, and on what was the T cell factor acting. Both nude mice and rats are able to form abscesses in response to *B. fragilis* challenge, suggesting that T cells are not necessary for abscess formation. It is known that nude animals do have early T cell precursors, however. Treatment of mice with low doses of cyclophosphamide abolished their ability to form abscesses, and reconstitution of the cyclophosphamide-treated animals with $\text{Ly-1}^+ \text{2}^+$ T cells restored this ability. Thus T cells are required at an early stage in the generation of *B. fragilis* abscesses, and the cell required for abscess induction is a relatively early precursor T cell as one might expect from the nude mouse data. It is presumed that this precursor T cell is being acted upon by the T suppressor cells in the prevention of abscess formation.

Although nude mice are capable of developing abscesses in response to challenge with *B. fragilis*, the transfer of the usual small number of immune T cells (2.5×10^6) or immune factor does not induce protection as in normal mice. This suggested that a second T cell might be required to induce abscess protection. This possibility was investigated with reconstitution experiments in nude mice. Transfer of 25×10^6 naive spleen cells into nude recipients reconstituted the ability of these mice to be protected against abscesses by the further transfer of 2.5×10^6 immune cells. The cells capable of reconstituting the nude mice were also $\text{Ly-1}^- \text{2}^+$ by phenotype.

Thus, it appears that abscess production and prevention in response to *B. fragilis* occurs by a T cell-mediated mechanism. Abscess induction requires a precursor-type T cell. Preliminary evidence suggests that the earliest cells entering the peritoneum in response to bacterial challenge may be lymphocytes. The mechanism by which they may act to elicit abscess formation is not yet identified. Prevention of abscesses require at least two T cells, of suppressor phenotypes, which communicate via a small polypeptide factor. These cells are antigen specific, but not MHC-restricted.

One additional question is the potential benefit of abscess formation to both the host and the bacterium. Animals which do not form abscesses do not develop diffuse overwhelming infection and death.

On the contrary, the *B. fragilis* in these animals is cleared without sequelae. This raises the possibility that abscesses are an adaptive mechanism by which the bacteria create a milieu favorable to survival rather than a particularly useful protective mechanism for the host.

BARE LYMPHOCYTE SYNDROME

Janice S Blum, Department of Microbiology and Immunology, Indiana University School of Medicine, Indianapolis, USA

Bare lymphocyte syndrome (BLS) encompasses a series of rare autosomal recessive disorders in which patients display low or null expression of HLA major histocompatibility proteins. Three types of BLS have been classified, with the severity of these disorders varying both in phenotypic HLA expression and loss of immune function. In BLS type I, low or no expression of HLA class I molecules are displayed on peripheral blood cells. The degree of immunodeficiency is most variable in BLS type I, with some individuals displaying essentially normal immunity. Type II BLS is defined as a reduction or complete loss of HLA class II protein expression on all cells. This disorder typically manifests as a severe combined immunodeficiency. In BLS type III disorders, both HLA class I and class II antigen expression are diminished and these individuals are severely immunodeficient. Studies of BLS patients have proven to be exceptionally informative, yielding insights into the effects of selective disruption of histocompatibility antigen function, as well as offering clues to the transcriptional and post-translational regulation of histocompatibility molecules.

Bare lymphocyte syndrome Type I

Class I histocompatibility antigens are constitutively found on all normal nucleated cells, however surface expression of these proteins may be down-modulated by viruses and in some tumors. In normal peripheral blood lymphocytes, diminished class I antigen expression with normal levels of class II proteins is an established hallmark of BLS type I. The levels of

class I antigen cell surface expression are quite variable among type I patients. Immunodeficiency does not always correlate with the level of class I antigen cell surface expression, and individuals with no or low class I antigen expression and no signs of immune dysfunction have been identified. Remarkably, Epstein–Barr virus transformation of B cells from patients with this latter phenotype resulted in partial restoration of class I expression. In other patients, severe immunodeficiency has been associated with BLS type I, including persistent bacterial and yeast infections, low numbers of peripheral blood T lymphocytes, and death within one year of birth. In the majority of these patients, the specific genetic factors responsible for the loss of class I antigen expression remain unclear.

Molecular studies to identify the genetic lesion in type I BLS have been carried out in patients with very low class I expression (1–3% of normal levels) and recurring sinopulmonary infections as well as bronchiectasis. In all cases, these individuals suffer from chronic bacterial infections and require antibiotic therapy. Investigations of two related type I patients revealed a truncation mutation in TAP2 (transporter associated with antigen processing), a molecule required for class I protein assembly and function. Class I heavy chains are synthesized by these patients; however these molecules are trapped intracellularly and only loosely associated with β_2 -microglobulin. In normal individuals, both surface expression of class I proteins and the stable association of class I heavy chains with β_2 -microglobulin is dependent upon binding of antigenic peptides.

Antigenic peptide delivery to nascent class I proteins typically occurs via a heterodimeric transporter consisting of TAP1 and TAP2 proteins localized in the endoplasmic reticulum. Murine and human mutant cell lines, as well as knockout animals lacking TAP proteins, display a phenotype almost identical to BLS type I patients. A low level of class I antigen surface expression is observed in both these BLS type I patients and the laboratory mutants. Studies with TAP-deficient cell lines indicate a small population of peptides exists within the endoplasmic reticulum which can bind class I complexes and promote stable transport and surface expression.

Clinical investigations of these type I BLS patients are remarkable in that susceptibility to pulmonary bacterial infections predominate. Peripheral blood CD8⁺ T lymphocyte levels are low and there appears to be no or very low natural killer cell function in these individuals. In contrast, high antibody titers against bacteria and viruses, as well as good responses to vaccination are found in these BLS type I patients. The enhanced frequency of respiratory tract bacterial infections in these patients suggests class I antigens on phagocytic cells such as macrophages must play a key role in immunity against these pathogens.

Bare lymphocyte syndrome type II

Class II histocompatibility antigens are expressed on professional antigen-presenting cells such as B lymphocytes, dendritic cells and macrophages. Expression of class II proteins on other cell types can be induced in response to cytokine treatment while a small number of viruses are capable of downregulating cell surface levels of class II antigens. In humans, heterodimers of class II α and β subunits are synthesized from highly polymorphic DR, DP and DQ loci encoded within the major histocompatibility gene complex. BLS type II is classically defined as a global loss of class II antigen expression. However, this definition has been broadened to encompass individuals with a loss of specific class II subunits as well as restricted class II expression on discrete cell types. Patients displaying very low or no class II proteins on their peripheral blood cells all have severe immunodeficiencies and suffer from chronic viral, bacterial, fungal and protozoal infections of the respiratory and gastrointestinal tract. Clinical onset of disease symptoms occurs within the first year of life and most patients do not survive beyond the age of four without therapeutic interventions such as bone marrow transplantation.

BLS type II patients display strong allograft rejec-

tion responses without immunosuppression, presumably because class I antigens are expressed by these patients along with, in some cases, low levels of class II molecules. Thus, the success of bone marrow transplantation is reduced in these individuals compared with other patients suffering from combined immunodeficiencies. Total numbers of peripheral blood T cells are normal in BLS type II patients, with very low numbers of circulating CD4⁺ T lymphocytes and enhanced levels of CD8⁺ T cells. This observation differs from the phenomena observed in mice lacking class II structural genes, where no single positive CD4 T cells mature. Possible explanations may include low expression of class II antigens on thymic cells in BLS type II patients, resulting in limited CD4⁺ T cell selection. Alternatively in humans, class I molecules in the thymus may play a role in the selection of CD4⁺ T cells. Most interestingly, following bone marrow transplantation of these patients, the circulating levels of CD4⁺ T cells remain low, yet immunity is restored. The implications of this finding are twofold: 1) that bone marrow-derived cells are not critical in the efficiency of thymic selection of T cells in these patients; and 2) that restoration of class II antigen expression on bone marrow-derived cells is critical to host defense. The number of peripheral blood B lymphocytes in BLS type II patients are normal, but antibody production is severely deficient in these individuals, presumably due to a lack of helper CD4⁺ T cells. In some individuals, autoreactivity including polyarthritis, eczema and psoriasis is also associated with the absence of class II antigen expression.

Analysis of BLS type II at a molecular level has led to the clustering of patients within multiple complementation groups, each group lacking a distinct gene regulating class II protein expression. In all cases of BLS type II, class II structural genes are intact, yet the transcription of mRNA from these loci is perturbed. Family studies suggest the genetic defects in all patients lie outside the major histocompatibility gene complex on chromosome 6. Fusion of patient cell lines with cells from normal individuals restores the expression of class II alleles derived from the BLS type II individual. This finding supports the conclusion that the defective gene is a *trans*-acting factor that controls the transcription of class II molecules. Fusion of B cell lines from different type II patients has firmly established three genetic complementation groups in this disorder (groups A, B and C (also termed II, I and IV respectively)). A mutagenized B cell line selected for its lack of surface class II antigens has been generated in the laboratory, and this cell comprises a fourth complementation group (group D or III). Additional complementation groups may exist, including patients selectively

expressing only a subset of class II subunits on distinct cell types. The majority of the patients identified fall within complementation groups A and B. In two of the complementation groups (B and C), patients also have substantially reduced class I antigen expression on peripheral blood cells. These individuals have been classified both as BLS type II and type III by different investigators. Immortalization of B cells from group B and C individuals using Epstein-Barr virus typically restores class I antigen surface expression to wild-type levels, but this viral transformation does not influence class II antigen transcription.

Molecular and functional studies have defined in part the genetic defects in BLS type II. *In vivo* analysis of class II promoters from type II groups B, C and D reveals a lack of transcription factors stably binding these regions of DNA, a phenotype referred to as 'bare' promoters. This result suggests that the class II gene promoter regions are inaccessible in these mutants. By contrast in BLS type II group A, normal occupancy of class II gene promoters is observed. To date, only the transcription factors defective in BLS type II groups A and C have been definitively identified. Using complementation cloning, the transcription factor defective in group A patients has been identified as a 1130 amino acid protein, CIITA (MHC class II trans-activator). Studies of several group A patients revealed point mutations, defects in exon splicing and genomic deletions in this protein. CIITA does not bind directly to DNA and may serve instead as a coactivator to facilitate the interaction of other transcription factors. Expression of CIITA in only group A mutants restores class II antigen expression and this transcription factor is critical in interferon γ (IFN γ) induction of class II antigen mRNA. CIITA is the only transcription factor at this time whose expression directly correlates with class II antigen mRNA levels in cells. For example, CIITA synthesis is ablated during the transition of B lymphocytes to plasma cells, coincident with a loss in class II antigen expression. The C-terminus of CIITA encodes a transcription-activating domain while the N-terminus confers specificity for class II promoter regions.

BLS type II group C patients have mutations in a 75 kDa transcription factor, RFX5. This protein serves as a key subunit in a multimeric complex termed RFX which binds the X-box region of class II promoters. Disruption of the RFX complex results in the 'bare' class II promoter phenotype of group C patients. These findings suggest another component of RFX may also be defective in group B or D patients which also display the 'bare' promoters phenotype. Questions remain as to whether RFX

plays any role in regulating class I antigen transcription in groups B and C, where reduced class I levels are observed on peripheral blood cells.

Both CIITA and RFX5 are essential for the synthesis of cell surface class II DR, DP and DQ alleles, however these transcription factors also have been shown to regulate the production of other molecules required for presentation via the class II pathway. The assembly and intracellular transport of class II proteins is mediated by a chaperone protein, the invariant chain. Despite its chromosomal location outside the major histocompatibility gene complex, the invariant chain shares some promoter elements with class II proteins. Expression of class II proteins and invariant chain is tightly linked in all cells and in BLS type II, synthesis of invariant chain mRNA is severely reduced but not completely ablated. The invariant chain must be proteolytically released from class II molecules to allow peptide binding and antigen presentation. Release of invariant chain peptides from the groove of class II proteins is mediated in endosomal/lysosomal compartments by HLA-DM. Functional and molecular analyses indicate that HLA-DM is also deficient in BLS type II patients. The absence of functional DM molecules renders cells unable to present exogenous antigens. While gene therapy and the replacement of class II structural genes has been discussed as a potential curative therapy for BLS type II, the requirement for multiple factors in antigen presentation suggests that restoration of the defective transcription factors is a more promising approach for this disorder.

Bare lymphocyte syndrome type III

Patients with BLS type III display no cell surface class II antigens as well as little or no class I proteins. The phenotype of these patients is most variable and many of these patients are classified as BLS type II due to their residual class I antigen expression. The immunodeficiency of these individuals mirrors that of BLS type II patients including susceptibility to chronic infections and early death without intervention. Peripheral blood levels of CD4⁺ T cells are low and antibody responses dramatically reduced in BLS type III.

While multiple patients with BLS type III have been identified, little progress has been made in elucidating the genetic defect(s) in these individuals. Class I antigen expression in some patients can be induced using IFN γ but this does not restore class II antigen levels. Molecular studies of a transformed fibroblast line from a type III individual revealed interferon treatment induced low levels of mRNA for class I heavy chain, β_2 -microglobulin and the proteasome

subunits LMP2 and LMP7. Interestingly, interferon induced normal levels of mRNA production for both TAP1 and TAP2 in fibroblasts from this type III patient. No induction of class II mRNA and little synthesis of invariant chain were observed in these interferon-treated cells. *In vitro* fusion of these type III fibroblasts with B cell lines from each of the four BLS type II complementation groups restored class II antigen expression. These results suggest that the defect in this type III individual is genetically distinct from BLS type II mutations. Elucidation of the defects in these cells will be important as approaches for gene therapy and transplantation biology are advanced.

BASOPHILS

Reuben P Siraganian, Receptors and Signal Transduction Section, Laboratory of Immunology, National Institute of Dental Research, National Institutes of Health, Bethesda, Maryland, USA

Basophils are a member of the granulocytes, the white blood cells in the circulation, and constitute less than 1% of the circulating leukocytes. Basophils share many features with mast cells. They both develop from a common bone marrow-derived hematopoietic precursor cell that is CD34⁺, have granules containing histamine, proteolytic enzymes and other inflammatory mediators, have high-affinity receptors for immunoglobulin E (IgE) (FcεRI) and are stimulated to release inflammatory mediators when they react with secretagogues. Therefore, both types of cell play a role in immediate hypersensitivity

and inflammatory reactions. However, there are a number of differences between basophils and mast cells. In contrast to mast cells, which mature in the tissues where they finally reside, basophils differentiate in the bone marrow and enter the circulation as mature, functionally active cells. Basophils have the capacity for chemotaxis and are recruited into tissues during inflammatory reaction. However, even in tissues they can be identified as basophils and there is no evidence that they transform into mast cells. Basophils are smaller than mast cells, are short lived (<2 weeks) and are probably end-cells. In contrast,

the mast cells are distributed in connective tissues, often adjacent to blood vessels and beneath epithelial surfaces (e.g. the gastrointestinal and respiratory tracts, and the skin). Mast cells normally do not circulate, are long lived and appear to retain the capacity to proliferate. Connective tissue-type mast cells in general contain much more histamine than basophils (a human basophil contains approximately 1 pg histamine). Unlike mast cells, chondroitin monosulfates are the major proteoglycan of basophils. There are also differences in the surface proteins found on basophils compared with those on mast cells. Studies in several mammalian species suggest an inverse quantitative relationship between basophils and mast cells, e.g. species that have abundant mast cells have few basophils. Humans however, have significant numbers of both mast cells and basophils.

The entry on mast cells describes the mediators released from basophils or mast cells, the high-affinity IgE receptor FcεRI, stimuli that activate the cells for secretion and the biochemical mechanisms of the release reaction. The present section describes the unique features of basophils and relies heavily on studies with human cells.

Morphology

Human basophils have a polylobed nucleus with condensed nuclear chromatin and absent nucleoli. They have little endoplasmic reticulum and free ribosomes. The cytoplasm contains a large number of granules that are heterogeneous in size. By electron microscopy some granules are filled uniformly with electron dense material, whereas others lack this dense material. When antigen is added *in vitro*, the basophils lose their oriented motility and extend pseudopodia. The degranulating basophils develop small cytoplasmic 'vesicles' that rapidly increase in size and coalesce. The granular membranes fuse with the plasma membrane, resulting in the development of narrow openings between the cell surface and individual granules. This results in the extrusion of membrane-free granular material through multiple openings in the circumference of the cell. However, there are some rare interconnected chains of granules opened to the exterior at a single point on the cell surface. The granule matrix is released as a whole to the outside, but the granule membrane is left behind. Frequently, membrane-free granular contents are seen attached to the cell exterior. The degranulation of mast cells is of the 'compound' type with granules fusing with each other, whereas in basophils most of

the granules fuse directly with the plasma membrane (Figures 1 A & B).

Basophils infiltrate and occasionally constitute a significant proportion of the total cells at sites of delayed hypersensitivity reactions. Such reactions are termed *cutaneous basophil hypersensitivity*. The T cells in such reactions probably release factors that are chemotactic for basophils and might also induce the basophils to degranulate slowly: the granules never fuse with the cell membrane, but lose their matrix in a 'piecemeal' manner over a period of days. Small packages of granular content appear to bud from granule membranes, traverse the cytoplasm and fuse with the plasma membrane, leaving completely degranulated cells.

Basophil releasability

Releasability of basophils refers to the variation in the extent of histamine release from the cells of different donors. The extent of histamine release from the cells of any one individual can vary from none to values as high as 90–100% of the total cellular content. There is good positive correlation between antigen-induced histamine release *in vitro* with the

Figure 1 Human basophils; (A) non-activated; (B) after degranulation. Photomicrographs kindly provided by Dr. Connie Oliver.

basophils of allergic patients and the extent of their symptoms. The releasability of the same cells can also vary with different secretagogues. There are also differences in the extent of release from basophils compared with mast cells. There is no correlation between the number of IgE molecules present on the surface of basophils and releasability. Recent evidence suggests that these differences in secretion are regulated by intracellular factors. For example, the cells of donors who are high responders release histamine with chemically cross-linked IgE dimers; whereas the cells of the donors who are low responders release with chemically cross-linked trimers, but very poorly with dimers. The sensitivity of cells to different stimuli can be modified by factors such as adherence of the cells to other cells or extracellular matrix proteins, by cytokines, by steroids or by dietary lipids that are incorporated into the membranes.

Cell desensitization

The cross-linking of the IgE receptors on the basophil or mast cell causes the activation of enzymes that result in secretion of mediators. Some of these biochemical reactions also regulate the extent of the release reaction. This process is called *cell desensitization*. Experimentally, desensitization is initiated by addition of the secretagogue under conditions that do not result in secretion, and after a defined incubation period the permissive conditions are restored. Desensitization is an active process, blocked by some pharmacologic agents, and is secretagogue-specific. The IgE receptor-mediated desensitization requires receptor aggregation, and can be either specific to the one antigen or for all IgE-mediated release reactions. At low cell surface IgE densities there is antigen-specific desensitization, whereas at high surface IgE levels there is desensitization for all IgE-mediated reactions. Desensitization is not due to the loss of cell surface antigen-specific IgE caused by endocytosis or shedding of IgE-antigen complexes. It is probably due to the decay of an unstable intermediate formed

by the cross-linked receptors interacting with a secondary component. The degree of desensitization probably regulates the extent of the release process.

The mechanism for mediator release is similar in the various cell systems studied, e.g. human mast cells, basophils or rat mast cells. All systems respond to the physiologically relevant stimulus of IgE-antigen. However, there are differences in the response to miscellaneous secretagogues that could be related to the presence of surface receptors, and there are differences in the rate of release with various cells. Some pharmacologic agents inhibit release from human basophils but not from mast cells. There are differences in the spectrum of mediators released by mast cells compared with basophils. In contrast to mast cells, human basophils release very little, if any, of the cyclo-oxygenase-derived products of arachidonic acid such as prostaglandin D₂. However, both mast cells and basophils release the leukotriene C₄. Mast cells but not basophils release the enzyme tryptase. There is little evidence to suggest that the secretory process is fundamentally different in the basophils compared with that in the mast cells.

Calmette and Guérin first described bacille Calmette–Guérin (BCG) in 1908. A bovine strain of *Mycobacterium tuberculosis* was grown on a piece of potato cooked at 70°C in bile containing 5% glycine. After 231 subcultures on this special medium and 13 years later, the bacilli were found to be nonpathogenic, but otherwise indistinguishable from the virulent strain. In 1921, this bacillus was first advocated as a live vaccine against tuberculosis (TB). Since then, BCG constitutes one of the mainstays of any TB control program. Evidence for successful vaccination is development of a delayed-type hypersensitivity reaction to a purified protein derivative (PPD) of *M. tuberculosis*.

Recommendations, administration and efficacy

The inconsistent policies among countries with regard to the indication for administering BCG vaccine reflect the contradicting and inconclusive data on the prevention of TB and the drawback of a resultant tuberculin seroconversion preventing the interpretation of the tuberculin skin test.

BCG is presently recommended in the USA for tuberculin-negative infants and children who have continuous exposure to isoniazide- and rifampin-resistant active TB, who cannot take isoniazid and are exposed to TB, or who belong to population groups with rates of new *M. tuberculosis* infections exceeding 1% per year. Vaccination is also advised for groups residing in high-prevalence areas such as military and foreign service personnel. Vaccination should be avoided in immunosuppressed individuals, with special regard to patients with established human immunodeficiency virus (HIV) infection because of the increased risk of disseminated infection.

The administration protocol recommended by the World Health Organization's expanded program is a single dose at birth. However, this recommendation is not implemented universally; for example,

in the UK a single dose is administered at the age of 13, whereas in eastern Europe repeated doses are given through childhood.

The efficacy of BCG against TB has been debatable since its initial use in 1921, although, to date, well over 3 billion doses have been administered. A recent comprehensive meta-analysis from 14 prospective trials and, separately, 12 case-control studies, addressing the efficacy of BCG, pointed towards an overall protective effect of 50% against TB infections. The protective effect against pulmonary and disseminated infection was 78%, against tuberculous meningitis 64% and against death 71%.

Antigenic properties and immunologic aspects

The mycobacterium is an acid-fast, slow-growing bacillus. Most of its antigens are firmly attached to the cell wall. These have been classified into three groups: 1) antigens common to all mycobacteria, which can also be found in other bacteria such as *Listeria*, *Corynebacterium* and *Nocardia* spp.; 2) common antigens present on slow-growing bacteria; 3) species-specific antigens. Most studies on the soluble antigens have been based on vigorous experimental methods by which the cell wall was disrupted and solubilized. This crude antigen preparation was found to be a nonspecific stimulant of cell-mediated immunity, as well as a powerful adjuvant to vaccines used in experimental animals.

Repeated injection of Freund's complete adjuvant containing killed mycobacteria results in a response resembling autoimmune disorders (the so-called adjuvant arthritis in rats). BCG itself can induce non-specific resistance to certain infections (or enhancement of others) and tumor growth suppression, attributed to various influences of the vaccine such as enhancement of macrophage cytotoxicity, increased production of natural killer cells, cytokines and cytotoxic T cells. Most of the above-mentioned properties are related to the high lipid content of the bac-

teria, up to 40% of its dry weight. These lipids include a variety of biologically active substances: trehalose 6,6'-dimycolate or 'cord factor', neutral red reactive sulfolipid, 6-O-methylglucose lipopolysaccharide, phosphatides and waxes. A group of substances which have been studied extensively are the mycolic acids. β -Mycolic acid is typical of BCG. It consists of three aliphatic chains of 11–28 carbons, linked by ester or hydroxyl residues to extensive hydrocarbon chains with a carboxyl side-chain at the link and at the end of the chain. A cyclopropyl group is present between the first two short chains. In the cell wall, these molecules are connected to sugars, containing arabinose and galactose, and with wax D. This complex is the molecule that gives the adjuvant activity. The nonspecific immune stimulation has been used in cancer management. Animal studies have demonstrated tumor regression following repeated local BCG infection. Viable BCG cells, injected into metastases of human malignant melanoma, led to marked tumor regression. Probably the most abundant use of BCG in cancer therapy is in bladder cancer. Intravesical administration is used for three purposes: 1) adjunctive therapy as a single treatment after complete tumor resolution to prevent

tumor cell implantation and recurrence; 2) prophylactically, in repeated doses to prevent *de novo* recurrence of tumor following complete excision; 3) therapeutically, in repeated administrations to treat residual unresected tumor. Known adverse effects include regional adenitis, disseminated BCG infection and osteitis due to the BCG organism.

BEHAVIORAL REGULATION OF IMMUNITY

Nicholas Cohen, Jan A Moynihan and Robert Ader, Center for Psychoneuroimmunology Research and the Departments of Microbiology and Immunology and of Psychiatry, University of Rochester Medical Center, Rochester, New York, USA

Although immune responses can readily occur and be analyzed *in vitro*, the immune system normally functions in an intact organism where it has the opportunity to interact with other physiological systems. A significant body of recent data points out that indeed such interactions do occur *in vivo*. For example, the central nervous system (CNS) is in dynamic communication with the immune system. Lymphoid tissues are richly innervated, and abrogation of this sympathetic innervation alters expression of natural and acquired immunity. Cells of the CNS produce proinflammatory cytokines (e.g. interleukin-1 (IL-1) and IL-6), and mitogen- or antigen-stimulated lymphocytes produce different hormones (e.g. proopiomelanocortin-derived peptides, growth hormone, prolactin, luteinizing hormone) and neuropeptides (e.g. substance P, vasoactive intestinal peptide). Lymphocytes and macrophages

express cell surface receptors for a diversity of hormones and neuropeptides, suggesting autocrine and paracrine regulation by these molecules. Experimental manipulation of hormone- or neurotransmitter-immunocyte receptor interactions can evoke alterations in immunologically relevant events such as lymphocyte proliferation, activity of natural killer (NK) cells, production of antibody, synthesis and release of cytokines, and expression of cytokine receptors.

There is now incontrovertible evidence that the immunomodulatory interactions between the CNS and the immune system can be 'regulated' by the behavior of the organism. Such evidence has been provided by predominantly phenomenological studies on the influences of classical (Pavlovian) conditioning and on the effects of 'stress' on immunity.

Pavlovian conditioning and immunomodulation

Classical (Pavlovian) conditioning is perhaps the first behavioral approach that has been used experimentally to reveal a relationship between the CNS and the immune system. In the classical Pavlovian paradigm, a stimulus (e.g. food) that unconditionally elicits a particular response (salivation) is repeatedly paired with a neutral stimulus that does not elicit that same response. Eventually, the neutral stimulus becomes a conditional stimulus, in that it will elicit salivation in the absence of food, the unconditional stimulus. Since Pavlov's experiments in the 1920s, a wide range of behavioral, physiologic and pharmacologic processes have been conditioned in a wide diversity of species. The first conditioning studies that involved nonspecific arms of the defense system were conducted in the Soviet Union in 1926, as extensions of Pavlov's work on the conditioning of physiologic responses. In these early studies, Metalnikov and Chorine conditioned an increase in polymorphonuclear leukocytes (PMNs) in a peritoneal exudate by repeatedly pairing the intraperitoneal injection of foreign material, in guinea pigs, with the scratching or heating of the animals' skin. After multiple pairings, and after the number of PMNs returned to baseline levels, re-exposure to the conditional stimulus alone was reported to evoke an increase in the number of PMNs. Several variations on these types of experiments, plus those in which increased levels of specific antibody were attributed to conditioning, appeared in the Russian literature in the next decade and then again in the 1950s.

The first rigorously controlled and immunologically relevant conditioning experiments in the West were published in 1975 by Ader and Cohen. In their initial study, rats were subjected to a single learning trial in which an injection of cyclophosphamide (CY), a potent immunosuppressive drug that served as an unconditional stimulus, was paired with the consumption of a novel, distinctly flavored saccharin (SAC) solution, the conditioning stimulus. When rats conditioned in this fashion were re-exposed to the conditional stimulus at the time of antigenic challenge, conditioned immunopharmacologic effects were revealed by a significantly depressed antibody response relative to the appropriate controls (i.e. nonconditioned animals, or conditioned animals that were never re-exposed to the conditional stimulus). Similar and subsequent conditioning protocols involving mice as well as rats, CY or other immunosuppressive drugs as unconditional stimuli, and different novel tastes as conditional stimuli, have revealed a conditioned: depression of

graft-versus-host reactions; enhancement of delayed hypersensitivity responses; depression of humoral immune responses to thymus-independent as well as thymus-dependent antigens; and depression of mitogen- and alloantigen-induced lymphocyte proliferation, heart and skin allograft rejection, plasmacytoma growth, NK cell activity, numbers of white cells and arthritic inflammation.

Exposure of conditioned animals (conditioned by pairing SAC with CY) to the conditional stimulus appears to create an immunomodulatory environment. This was suggested by experiments in which conditioned rats, exposed to the conditional stimulus a few weeks before they were immunized, still displayed a conditioned immunosuppressive response to the antigen. More direct evidence that conditioning alters the internal milieu (and may primarily affect T cells) comes from the use of classic lymphocyte transfer and cell-mixing protocols by Gerczynski. In these, and in other conditioning studies in which the unconditional stimulus was the injection of either CY or some other immunosuppressive drug, it seems reasonable to propose that the actual unconditional stimuli being perceived by the CNS as deviations from homeostasis are some secondary or tertiary immunologic consequence(s) of the direct effect of CY on the lymphocyte (e.g. changes in lymphocyte number and/or traffic).

That conditioned immunopharmacologic effects are of biological importance is apparent from Ader and Cohen's observations that the development of a systemic lupus erythematosus (SLE)-like autoimmune disease in (NZB $\times$ NZW) F_1 hybrid mice could be markedly delayed by treating animals under a partial schedule of pharmacologic reinforcement. That is, by substituting conditional stimuli that had been paired with CY for a proportion of the trials on which animals would normally have received active drug therapy, conditioned mice showed a significant delay in the onset of lupus using a cumulative dosage of CY that was, by itself, insufficient to alter the course of the autoimmune disease. Moreover, conditioned mice repeatedly re-exposed to the taste stimulus that had been paired with CY following the termination of active drug therapy survived significantly longer than conditioned animals that received no 'medication'.

Although in the not-too-distant future, conditioned immunopharmacologic effects may prove to be significant in clinical situations where one wishes to reduce the amount of actual drug administered to a patient with an autoimmune disease or an organ transplant, this model of conditioned immunosuppression may be of limited help in trying to understand the basic impact and physiology of

conditioning on 'normal' immune responses. More revealed models would be those in which immune responses are altered in animals that are conditioned by pairing a conditional stimulus with a naturally occurring immunologic response modifier (e.g. a cytokine) or with a substance that itself unconditionally elicits an immune response, namely an antigen. Since conditioning is an example of feed forward control in which the organism reacts physiologically based on an anticipated need, a conditioned immune response in the absence of an externally administered cytokine or an immunogenic concentration of antigen would indeed highlight the physiological importance of CNS regulation of immunity during the normal life of an organism. At this time, only a handful of such studies have been performed, and several of these have involved the conditioned release of histamine or protease II from mast cells of animals sensitized with protein antigens. In one study, however, a conditioned change in antigen-specific lymphocytes was reported. In this experiment, Gorczynski, Macrae and Kennedy repeatedly grafted CBA mice with allogeneic skin from C57BL/6J mice. During the 40 day interval between first, second- and third-set grafting, the number of cytotoxic T lymphocyte precursors (CTLp) specific for the alloantigens of the sensitizing donor increased and then returned to baseline levels. Each recipient mouse was anesthetized, shaved, had a graft bed surgically prepared on to which the skin allograft was placed, and was then bandaged. That is, the grafting procedure itself served as a complex of conditional stimuli. On the fourth (test) trial, animals in all groups were exposed to just the conditional stimuli (i.e. they were sham grafted). Only conditioned mice displayed an increase in CTLp in response to the stimulus conditions associated with grafting in the absence of an actual graft. In each of several replications of this experiment, only about half of the conditioned mice showed the conditioned change in CTLp. These 'responder' mice were then divided into subgroups that either experienced two extinction trials (unreinforced exposure to the conditional stimulus) or two additional learning trials (i.e. two separate trials in which there were pairings of the conditional and unconditional stimuli). All 'responder' animals that received additional conditioning trials displayed an increase in CTLp in response to the conditional stimulus; none of the 'responders' given extinction trials showed the conditioned response.

In a recent study by Ader and his colleagues, an enhanced antibody response provided the immunologic readout of a conditioning protocol in which antigen itself served as the conditioned stimulus. In

this study, injection of a very small amount of key-hole limpet hemocyanin (KLH) was paired with a novel taste on each of several learning trials. In between each learning trial, the serum antibody response increased and then decreased. On the test trial, mice were given an amount of KLH (0.5 ng) that only elicited a modest antibody response by itself, but when it was given to conditioned animals in association with the conditional stimulus, KLH-specific antibody titers increased significantly over baseline. To confirm that this was a *bona fide* conditioned response, mice were pre-exposed to the conditional stimulus before the initiation of the first and subsequent learning trials. When such animals were presented with the small antigen boost plus the conditional stimulus, they did not produce antibody, an observation totally consistent with learning theory.

Given that we do not fully understand the mechanisms that underlie these examples of conditioning, one can only speculate about: 1) the nature of the neurochemical consequences of various conditional stimuli in the nervous system; 2) which (and how the) relevant internal physiologic consequences of an antigenic, pharmacologic or physical unconditional stimulus become associated internally with the neurologic sequelae of a conditional stimulus; and 3) how presentation of the conditional stimulus evokes the immunomodulatory responses that many investigators have observed. Regardless of our ignorance of the constellation of mechanisms that may be involved in conditioned alterations of immunity, it is clear that, since learning involves higher centers of the brain, the ability to effect changes in immune responses by conditioning must mean that, *in vivo*, the immune system receives and responds to signals (either directly and/or indirectly) from the CNS.

Stressor-associated regulation of immunity

Stress, as defined by Hans Selye, is the response to deviation from the normal resting condition (i.e. homeostasis). It is generally accepted that stressor administration causes complex neurologic and neurochemical changes as the host attempts to adapt to the demands of the situation. These CNS changes regulate many physiologic processes, including those involved in the generation of an immune response. Immunomodulatory 'stress' protocols have involved different periods of exposure to either physical stimuli (e.g. electric shock, rotation, restraint, temperature, noise) or so-called psychosocial stressors (e.g. differential housing, maternal separation and handling in experimental animals; bereavement, divorce

and school examinations in humans). Immunologic outcomes measured in such studies have been: the development of primary and secondary antibody and cell-mediated immune responses to experimental antigens, microbial pathogens and tumor cells *in vivo*; the numbers of B cells and T cell subsets in various lymphoid compartments; the magnitude of mitogen- and/or antigen-induced lymphocyte proliferation *in vitro*; the production of, and response to, cytokines; NK cell cytotoxicity; and macrophage activation. Considering the variability among these studies with respect to the nature, duration and intensity of the stressor, the age, sex, species and strain of the stressed organism and the parameters of the immune function studied, it is not surprising that different effects of stress on immunity have been reported. Thus, the same stressor can effect enhancement or suppression of different immune responses; different stressors can have different effects on the same parameter of immunity; the same stressor applied for varying periods of time may have different effects on the same parameter of immunity; and changes in a single parameter of immunologic reactivity in response to different stressful stimuli are not necessarily unidirectional. By and large, however, stress in experimental animals and humans has been reported to depress the particular parameters of immunity that were being examined.

Stress has a variety of neuroendocrine effects, and immune responses are affected by the neuroendocrine milieu in which leukocytes function. However, it is far from clear which (and how) stress-associated neuroendocrine changes are responsible for which stress-associated immunomodulatory events. For example, the hypothalamo-pituitary-adrenal (HPA) axis is activated during stressful situations, and there are numerous reports of stress-induced adrenocortically-mediated immunosuppression. However, there are also several reports of stress-induced alterations of immunologic reactivity that occur in adrenalectomized animals. Although hypophysectomy obviates the effects of stress on some measures of immune function, stress-induced suppression of others are potentiated by this procedure. Because of the involvement of the HPA axis in stress-induced analgesia, many investigators have looked for, and found, a role of endogenous opioids in stress-associated immunomodulation in a variety of species including fish, mice, rats and humans. However, not all stress effects on immunity can be blocked by naloxone or naltrexone and/or mimicked by exogenous opioids such as endorphins and morphine. Finally, although levels of catecholamines and other neurotransmitters are known to be altered in response to stress, and many studies have revealed a

role of norepinephrine on immune function, few studies have attempted to correlate stress-induced changes in plasma catecholamines with altered immune function.

For immunologists, the fact that physiologic responses to stressors are immunomodulatory has practical implications that relate to experimental design as well as experimental theory. For example, putative pheromones from stressed (footshocked) mice conveyed to KLH-immunized recipients can affect cytokine production by lymphocytes *in vitro* and the immune responses they regulate *in vivo*. An extension of these observations to a situation in which manipulations of mice in an animal room can be communicated to and effect immune responses of other animals in that same room is not an unwarranted assumption. A second example of practical import for immunologists is that the differential housing of mice (housed one versus four per cage from the time of weaning) reproducibly and significantly influences antigen-stimulated *in vitro* production of T_H1- and T_H2-derived cytokines by splenocytes from mice immunized with either KLH or herpes simplex virus (HSV).

In the pheromone studies mentioned above, the immunologic effects on recipients of 'stress odors' occurred in a manner consistent with the theory that depressed cellular but enhanced humoral immune responses in pheromone-exposed BALB/c mice are reflective of an altered 'balance' between production of T_H1 and T_H2 lymphocyte-derived cytokines. However, the immunologic effects of differential housing on immune responses of either BALB/c or C57/BL6 mice to either KLH or HSV do not fit all predictions inherent in the theory of a differentially 'balanced' cytokine response and strain-associated dominance of humoral or cellular immunity. That is, regardless of strain or antigen, individually housed animals produce more antibody, have greater delayed-type hypersensitivity responses, and make more interleukin-2 (IL-2), IL-4, interferon γ (IFN γ) and IL-10 than do group-housed animals.

The observations that physical and psychosocial stressors can modulate immunity on the one hand, and modify disease progression on the other, has led to popularization of the idea that stress plays an important role in the pathogenesis of immunologically relevant diseases (e.g. cancer, viral and bacterial infections, autoimmunity, allergy). At this time, however, the cause-effect relationships between a stressor-altered immune system and disease progression must be viewed more as a reasonable and attractive hypothesis than as hard fact. Specifically, it has yet to be reproducibly documented in experimental animals (let alone in humans) that stress-

associated alterations of some facet of immunocompetence are, at least partially, responsible for disease pathophysiology.

Immunity can modulate behavior

The previous material has reviewed data indicating that behavioral triggers of the nervous system can regulate immunity. Several lines of evidence also indicate that components of an immune response can also signal the CNS. For example, many investigators have reported electrical changes in the hypothalamus following the administration of antigen. Others have reported that IL-1 stimulates release of corticotropin-releasing hormone from the hypothalamus into the hypophyseal portal circulation, where it can then activate the HPA axis. Moreover, the response to antigenic stimuli appears to be associated with the release of neurotransmitters and hormones produced by lymphocytes themselves. Finally, evidence suggests that these and/or other signals from an activated immune system may be directly or indirectly signaling the CNS to actually modify the behavior of the organism. The most intriguing observations are those suggesting that the immunologic abnormalities of the lupus-prone strains of congenic MRL mice modify (directly or indirectly) the animals' behavior, which in turn can act to 'correct' homeostatic imbalances within the immune system.

Summary

The current data on conditioned and stress-associated alterations of immunologic reactivity produce compelling evidence of a fundamental integration of behavioral, neuroendocrine and immune processes of adaptation. It now appears that, like all other biological systems functioning in the interests of homeostasis, the immune system is integrated with other psychophysiologic processes and therefore is subject to regulation or modulation by the brain. Conversely, immune processes seem to have implications for neural and endocrine function, including behavior. As such, they provide evidence for the *in vivo* bidirectionality of interactions between the immune system and the central nervous system.

BENCE JONES PROTEINS

Jean-Louis Preud'homme, Laboratory of Immunology and Immunopathology (CNRS ESA 6031), Poitiers University Hospital, Poitiers, France
Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Bence Jones proteins (BJP), initially known as urinary proteins precipitating at 56–64°C and redissolving on boiling, are now defined as monoclonal free immunoglobulin (Ig) light chains (LC) (polyclonal free LC that may be found in urine are not BJP). Their characterization and quantification is of importance because of their diagnostic and prognostic significance.

Characterization

Bence Jones proteins are usually present in urine as monomers and dimers. Search for BJP often requires a concentration step which is best achieved by vacuum dialysis preferably of daily urine. This results in minimal denaturation and does not bias against certain proteins (including some BJP). Electrophoresis of concentrated urines typically shows a narrow band with a mobility generally different from that of the entire monoclonal Ig which may be present in the serum. Bence Jones proteins are sometimes heterogeneous in charge and are easily and reliably quantified by scanning the electrophoresis. Immunoelectrophoresis shows one or several contiguous narrow precipitating lines with the relevant anti-LC serum and no reactivity with anti-heavy chain sera. Being monoclonal in origin, the BJP are of either κ or λ type. When part of a κ type BJP displays a fast migration, this usually results from an interaction with α_1 -antitrypsin. Immunofixation may be useful in the diagnosis of BJP. Western blotting of high-resolution agarose electrophoresis followed by detection with enzyme-coupled Ig-specific antibodies is more sensitive and more accurate.

Bence Jones proteins are detectable in the serum when they are secreted in very large amounts, when they polymerize and in the case of renal failure. Antisera that react with free LC and not with LC in whole Ig molecules may be helpful.

Diagnostic significance

Normal plasma cells most often produce balanced amounts of heavy and light chains. In contrast, malignant plasma cells often secrete free LC. Hence, the presence of significant amounts of BJP ($\geq 0.3 \text{ g l}^{-1}$ of urine) is indicative of malignancy. Minute amounts of BJP detected after $1000 \times$ concentration of proteins present in urine in physiologic concen-

trations are also mostly observed in malignant diseases. In myeloma, BJP are found as the only monoclonal Ig in about 20% of cases. In IgD myeloma (of the λ type in 9 out of 10 cases), there is usually a large output of BJP, whereas the serum monoclonal IgD is often present in small amounts. Hence, the finding of an apparently isolated λ BJP should lead to a search for IgD myeloma. Bence Jones proteins may be observed in B cell lymphomas and leukemias, in small amounts in virtually every patient with Waldenström macroglobulinemia, and in about 50% of cases of μ heavy chain disease.

Pathogenetic implications

Bence Jones proteins play a direct role in myeloma-associated kidney disease and their measurement is of important prognostic significance. They are also involved in visceral diseases featuring tissue deposition of LC-related material. Combined study of serum and urine by sensitive methods reveals evidence of BJP in almost all cases of AL (amyloid light chain) amyloidosis. In LC deposition disease, tissue deposits of monoclonal LC (and of monoclonal heavy chains in some patients) correlate with the presence of a monoclonal population of bone marrow plasma cells, whatever the clinical context. In some cases, the LC are normal-sized and present in urine but in about 60–70% of patients they display an abnormal (short or enlarged by glycosylation) size, polymerize and are undetectable in serum and urine. In both instances there are numerous mutations in the variable (V) regions of the LC, especially in the hypervariable regions (with probably a direct pathogenic role), together with an abnormal subgroup distribution (V κ IV predominance). V region abnormalities, with a V domain (of the V κ I subgroup) highly resistant to proteolysis and prone to readily form crystals, are also involved in myeloma-associated Fanconi syndrome.

BIOZZI MICE

Gino Doria, Laboratory of Immunology, AMB-BIO-MED, ENEA, Rome, Italy

Biozzi mice are lines of mice genetically selected for high (H) or low (L) antibody responsiveness. From the initial study in 1968 by Biozzi and his group, five different selections, referred to as selections I, II, III, IV and V, were carried out by Biozzi and colleagues.

The character selected was the maximal or minimal antibody response at a given time after an optimal dose of the various antigens used in the different selections. The antibody response was measured by direct or passive agglutination. In every population the frequency of the log₂ of the agglutinin titer (the highest doubling serum dilution giving a positive agglutination) was normally distributed.

Except for selection II, two non-cross-reactive antigens were alternated in consecutive generations in order to avoid the specific interference of maternal antibodies passively transmitted to the progeny. In selection I the antigen used was sheep red blood cells (SRBC) for the first six generations; subsequently SRBC and pigeon erythrocytes were alternated at each generation. In all generations of selection II, mice were immunized with SRBC but the period between weaning and immunization was prolonged to allow elimination of the maternal antibodies. Selections III and IV were carried out for responses to flagellar and somatic antigens, respectively, of two non-cross-reactive *Salmonellae* (*S. typhimurium* and *S. oranienburg*) given alternately. The antigens used for selection V were bovine serum albumin and rabbit gammaglobulin, alternately.

High and low antibody responder lines were produced by bidirectional selective breeding. Starting from a foundation population (F0) of outbred albino mice displaying great variability in antibody response, the two-way selective breeding was performed for maximal or minimal antibody response and repeated in each consecutive generation. Assortative

mating of the highest responder mice produced the H line, while that of the lowest responder mice produced the L line. In each line several pairs were culled at each generation and were issued from different families to delay the increase in consanguinity. The two lines diverged progressively until the maximal interline separation was reached at a given generation (selection limit).

According to the principles of quantitative genetics as applied in these studies, at the selection limit the two lines are considered homozygous for all independent loci controlling the antibody response, owing to the progressive accumulation of high-effect alleles in the H line and low-effect alleles in the L line.

The total response (TR) to selection is the interline difference at the selection limit, while the response (R) to selection is the difference between the mean values of two successive generations of each line. The selection differential (S) is the difference between the mean of the selected parents and that of the total population out of which they have been culled. The mean realized heritability (h^2) is calculated by the linear regression coefficient of cumulated R versus cumulated S over the generations between F0 and the selection limit, and is equal to R/S .

Once the selection limit was attained, the following interline hybrids were derived from H and L parents: (H × L) = F1; (F1 × F1) = F2; (F1 × H) = BcH; (F1 × L) = BcL. Using mean values ($\bar{x}$) and variances (V) of the character measured in these mouse populations, relevant genetic parameters were estimated. The total additive effect (a) of all the homozygous loci in H and L lines at the selection limit in the absence of dominance is given by

$$a = \frac{1}{2} (\bar{x}_H - \bar{x}_L).$$

The global dominance deviation (d) in F1 hybrids is given by

$$d = xF1 - \frac{1}{2}(xH + xL).$$

The dominance effect is d/a .

The environmental variance (VE) is the mean phenotypic variance of the genetically homogeneous populations: H and L lines at the selection limit and their F1 hybrids. Therefore,

$$VE = \frac{VH + VL + VF1}{3}.$$

The phenotypic variance of the genetically heterogeneous populations, F0, F2, BcH and BcL, is contributed by both genetic and environmental factors. The variance of F2 hybrids is

$$VF2 = VA + VD + VE$$

where VA is the additive variance and VD the dominance variance. The summed variance of the two backcrosses ($VBcH + VBcL$) is

$$VBcs = 2(\frac{1}{2}VA + VD + VE) = VA + 2VD + 2VE.$$

Since

$$VF2 - VA = VD + VE, \text{ then } VBcs = 2VF2 - VA.$$

It follows that $VA = 2VF2 - VBcs$.

Knowing VA , the number (n) of independent loci controlling the character is calculated as

$$n = \frac{a^2}{2VA}$$

Since the h^2 value results from the additive effect of homozygous loci occupied by either high- or low-effect alleles, the heritability of the character can also be measured in the progeny of interline crosses (F2 or backcrosses) by the ratio of the additive variance to the total phenotypic variance, as follows:

$$h^2 = \frac{VA}{VA + VD + VE}.$$

Comparison of the immunogenetic parameters in the five selections (Table 1) revealed a remarkable

similarity in the total response to selection, selection limit and realized heritability. Only in selection V was the total response greater and attained after fewer generations. The number of independent loci controlling antibody responsiveness differed in the five selections, owing to the different nature of the antigens and immunization procedures used. Mapping studies associating polymorphic microsatellite markers with antibody response in selection I have shown that some segregating loci are linked to genes on chromosomes 4 and 8 but also to genes certainly involved in major immune functions, such as genes on chromosome 6 coding for the TCR β chain, Ig κ and CD8, genes on chromosome 12 coding for the Igh allotypes, and genes on chromosome 17 coding for the MHC, TNF α , TNF β , C2 and C4.

The antibody response in H, L lines, and interline hybrids of the five selections (Table 2), indicates that the additive effect (a) was similar, whereas the dominance deviation (d) was different in all selections, yielding a different dominance effect (d/a) in each selection. Thus, the high responsiveness was incompletely dominant, to a variable extent, in selections I, II, III and IV, whereas it was incompletely recessive in selection V.

In all selections, the high or low effects of the alleles at the n loci are not limited to the selection antigen but may also influence the immune response to immunogens non-cross-reactive with the selection antigen. This multispecific effect is not general, as the difference in antibody response between H and L responder mice to various unrelated antigens may be identical, smaller, insignificant or even inverse as compared with the difference in response to the selection antigen. Comparison of the results obtained in the five selections indicates that the multispecific effect is large in selections I and III, intermediate in selections II and IV and restricted in selection V.

Selective breeding was also carried out for mitotic responsiveness of lymph node cells to *in vitro* stimulation by phytohemagglutinin (PHA). The selection limit was reached after ten generations, the realized heritability was 0.24, the low responsiveness was incompletely dominant, and the character was under the control of 10–19 independent loci. These H and L responder mice also displayed a similar difference in responsiveness to concanavalin A, in mixed lymphocyte reaction and graft-versus-host reaction, but produced the same antibody titer when immunized with SRBC.

Whether selective breeding for a polygenic character, such as antibody or mitotic responsiveness, also affects lifespan was investigated in selections I, II, III and PHA. The lifespan was longer in H than in L mice of selections I and II, but no difference was

Table 1 Genetic parameters of the five selections

Selection	TR	Selection limit	h^2	n
I	7.8	F16	0.20	9–11
II	6.7	F13	0.21	5–7
III	6.3	F16	0.20	4–7
IV	6.5	F13	0.21	2–4
V	9.8	F7	0.22	2–4

found between H and L mice of selections III and PHA. The positive correlation between antibody responsiveness and lifespan was further analyzed in interline hybrids of selection II and found statistically significant in most of these mouse populations. Moreover, the lifespan of the last 30%, 20% and 10% survivors, which are scarcely affected by early disease-induced mortality and mainly influenced by genes acting on the rate of physiologic aging, appeared as a polygenic character regulated by 3–7 independent loci. Noteworthy, the long lifespan was incompletely dominant in the total population, but was longer in the last 30% and completely dominant in 20% and 10% survivors (Table 3). Thus, the results of this analysis suggest that antibody responsiveness and lifespan are polygenic traits regulated by a small number of the same or closely linked loci.

The incidence of spontaneous malignant lymphomas was markedly higher in L than in H mice of selections I, II and PHA, whereas no difference was found between L and H mice of selection III.

Improvement of the effect of selection was obtained by assortative breeding from two foundation populations, F0H and F0L, each of which was produced with balanced frequency of the gene pools from the H or L lines of selections I, II, III, IV and V. After 16 generations of selection for primary or secondary responses to all the antigens used in the original five selections the difference between H and L lines in antibody responsiveness was remarkably amplified and the multispecific effect of the selection was generalized to several antigens. These results, obtained in selection GP for general-primary and selection GS for general-secondary responses, suggest that more genes with upward effects had accumulated in H mice or, rather, more genes with downward effects had accumulated in L mice during both selections. The influence of immune responsiveness on lifespan and disease susceptibility was also investigated in H and L mice of the GS selection at the F16 generation. It was found that the cumulative mortality rate is remarkably higher in L than in H mice, the difference being accounted for mostly by

malignant lymphomas that are the major cause of death in L mice. The interline difference in lifespan and lymphoma incidence in mice of the GS selection is much larger than that observed in mice of selections I and II.

The cellular modifications of the immune system brought about by selection are not completely understood. At present a major difference, between selections I and II on one hand and selections III and IV on the other hand, concerns macrophages. In selections I and II macrophages of L mice show a more active antigen catabolism and less efficient antigen presentation than macrophages of H mice. Conversely, no differences in macrophage activities were found between H and L mice of selections III and IV. Natural killer (NK) cell activity was found to be lower in L than in H mice of selection I but higher in L than in H mice of selections II and III. Expression of genes regulating antibody responsiveness in lymphocytes was mostly investigated in H and L mice of selection I. It was found that high or low effect genes accumulated in H or L mice were expressed in B cells (higher rate of cell proliferation and differentiation in H than in L mice) and at the level of all Ig isotypes but not in T cells involved in helper activity, skin graft rejection, graft-versus-host reaction, PHA mitotic response, and delayed-type hypersensitivity. However, a limiting dilution assay revealed higher numbers of T cells mediating delayed-type hypersensitivity in H than in L mice.

The significance of the humoral and cellular changes induced by selective breeding stems from studies on innate and acquired immunity to infections in selection I. The conclusion from these studies is that H mice are more resistant than L mice to extracellular pathogens such as *Pneumococcus*, *Klebsiella*, *Trypanosoma* and *Plasmodium*, which are sensitive to the consequence of antibody binding, whereas L mice are more resistant than H mice to

intracellular pathogens such as *Salmonella*, *Brucella*, *Yersinia*, *Mycobacterium* and *Leishmania*, which are sensitive to the bactericidal activity of macrophages.

The Biozzi experimental approach of bidirectional selective breeding has also been used to investigate the polygenic control of inflammation and chemical carcinogenesis.

The application of bidirectional selective breeding to acute inflammatory reaction (AIR) yielded two lines of mice, one giving the maximal (max) AIR and the other giving the minimal (min) AIR. Both max AIR and min AIR were triggered by subcutaneous injection of polyacrylamide microbeads and measured by the leukocyte and serum protein accumulation in the exudate. Selection was started from a genetically heterogeneous foundation population produced by the intercrossing of eight inbred strains of mice and carried out by assortative mating of extreme phenotypes. The response to selection in 11 consecutive generations was highly asymmetrical, as AIR markedly increased in the max line whereas it remained unchanged in the min line. The h^2 mean value in the AIR max line was 0.26 for leukocyte and 0.18 for protein concentrations. The response to selection and the large interline difference resulted from the interaction of 7–9 independent loci with additive effects. The difference between max AIR and min AIR lines is not limited to inflammatory responsiveness as max AIR mice are also more inclined to produce IgE and are more resistant to *Salmonella typhimurium* and to chemical carcinogenesis than are min AIR mice.

The polygenic control of chemical carcinogenesis has been studied by bidirectional selective breeding for susceptibility and resistance to two-stage skin carcinogenesis, initiated with 9,10-dimethyl-1,2-benzanthracene (DMBA) and promoted with 12-O-tetradecanoyl-phorbol-13-acetate (TPA). The selection was started from a heterogeneous population,

Table 4 Carcinogenesis induced in Car-S and Car-R mice at F10, and in their F1 hybrids after 49 days of promotion

Line	No. of mice	DMBA (μg per mouse)	TPA (μg per mouse)	Incidence (%)	Mean number of papillomas $\pm$ SE per treated mouse
Car-S	40	25	5	100	9.07 $\pm$ 0.70
	36	2.5	1	100	6.16 $\pm$ 0.69
	33	1.0	0.5	98	3.51 $\pm$ 0.42

Car-R	40	50	20	18	0.25 $\pm$ 0.10
	40	50	10	5	0.05 $\pm$ 0.03
	40	25	5	0	0.00 $\pm$ 0.00
F1	36	50	10	89	3.72 $\pm$ 0.64
	36	25	5	75	3.50 $\pm$ 0.56
	36	2.5	1	23	0.47 $\pm$ 0.24

SE, standard error.

as produced by the intercrossing of eight inbred strains of mice, and the character chosen for the assortative mating was the number of papillomas at the end of the promotion period. Susceptible (Car-S) and resistant (Car-R) lines of mice separated by ten consecutive generations of bidirectional selective breeding display a very large difference in responsiveness to carcinogenesis (Table 4). The dominance effect (d/a) = 0.38) measured in (Car-S $\times$ Car-R)F1 hybrids indicates that the susceptibility of papilloma induction is an incompletely dominant character. The difference between Car-S and Car-R lines is restricted to the skin, implying that the selected genes produce a tissue-specific effect.

BLOOD TRANSFUSION REACTIONS

C Paul Engelfriet, Central Laboratory of the Netherlands Red Cross
Blood Transfusion Service, Amsterdam, The Netherlands

In addition to the transmission of infectious diseases by donor blood, immunological reactions between antibodies in the blood of the patient, and sometimes in that of the donor, and the antigens against which

they are directed, may cause more or less dangerous transfusion reactions. The antibodies involved are alloantibodies against products of allelomorphic genes, but immunoglobulin E (IgE) antibodies

against nonhuman antigens also play a role. The various relevant antibodies and the reactions they may cause will be briefly discussed.

Alloantibodies against red cells

These include 'naturally occurring' antibodies, particularly anti-A and -B, and immune antibodies induced by previous transfusions and/or pregnancies. Except in exceptional cases (see below) blood transfusion reactions due to red cell antibodies should not occur. The correct determination of the ABO blood group of donor and recipient, correct antibody detection and cross-matching and correct patient identification should prevent such reactions. Because donor red cells are destroyed when a reaction is caused by red cell antibodies, such reactions are called hemolytic.

The signs and symptoms of the reaction are due on one hand to the liberation of hemoglobin and thromboplastic substances in stroma, and on the other to the activation of complement, leading to the liberation of C3a and C5a which increase vascular permeability, stimulate mast cells to liberate vasoactive substances such as histamine, and macrophages to liberate cytokines such as interleukin-1 (IL-1).

When ABO incompatible red cells are transfused the reaction is usually severe: the patient becomes restless and complains of a feeling of oppression, which is often accompanied by substernal pain. The patient may have abdominal pain and may vomit.

In serious cases renal function is seriously impaired and there may be uncontrollable bleeding. There is jaundice and hemoglobinuria. Reactions due to antibodies of other specificities are usually less severe, fever being the most common symptom, but jaundice and hemoglobinuria also quite frequently occur.

Exceptional cases

Delayed-type hemolytic transfusion reaction

Whereas the above hemolytic transfusion reactions begin during or shortly after a transfusion, a hemolytic reaction may also occur 3–5 days after a transfusion. In these cases the patient has been immunized in the past against a blood group antigen, but before the present transfusion is given the antibodies are either very weak or even undetectable. The transfused red cells induce a secondary immune response against the antigen and the antibody concentration rises so quickly that after 3–5 days there is enough antibody to destroy the donor cells. If the responsible antibodies are undetectable before the transfusion, the reaction cannot be prevented unless it is known that

antibodies were detected in the patient's serum on a previous occasion, in which case compatible blood must be given. In some cases the direct antiglobulin test may remain positive long after the donor red cells have been eliminated, due to the formation of cross-reacting or autoantibodies secondary to the alloimmune response.

Hemolytic transfusion reaction without detectable antibodies

Rarely a typical hemolytic transfusion reaction occurs while no antibodies are detectable at any time. It has been shown that in these cases the reaction must be due to alloimmunity against a particular red cell antigen. For example only the survival of C-positive red cells is shortened in a C-negative patient. Why anti-C is not detectable in the serum of such a patient and what the mechanism is which is responsible for the sometimes rapid destruction of the donor cells is unknown. Obviously, such a reaction cannot be prevented by routine laboratory investigations.

Red cell alloantibodies in the serum of a donor may be responsible for destruction of red cells of the patient, but this has only been described for potent Anti-A and/or B.

Alloantibodies against platelets

These are of two categories: HLA class I antibodies and platelet-specific ones. Whether transfusion reactions may develop as a result of the interaction of donor platelets and HLA antibodies has not been established. Antibodies against platelet-specific antigens may cause the following reactions.

Febrile reactions

These reactions follow a typical pattern. However, such reactions, in the vast majority of cases are caused by a reaction of antibodies with granulocytes and will therefore be described below.

Post-transfusion purpura

In this serious and, from an immunological point of view, interesting reaction, severe thrombocytopenia develops 5–7 days after a transfusion. The reaction occurs in patients, nearly always women, who have become sensitized to a platelet-specific alloantigen, usually as a result of pregnancies but occasionally by blood transfusion. The reaction is thus due to platelet-specific antibodies, anti-HPA-1a in the great majority of cases, but antibodies against other HPA antigens have also been involved. In this reaction, the patient's platelets, which are of course negative for

the alloantigen involved, are destroyed. The mechanism responsible for this destruction has not yet been definitely established. It may be due to the fixation of immune complexes consisting of alloantibodies and the antigen against which they are directed. These complexes may be formed with free platelet antigens present in the donor plasma or may be liberated after the destruction of donor platelets, or both. Possibly the attraction of different platelet glycoproteins for each other, e.g. GPIIb for GPIIIa, may be the basis of the fixation of such immune complexes to the patient's platelets. Another possibility is that during the secondary immune response against the alloantigen, cross-reacting or autoantibodies are formed which react with the patient's own platelets. Post-transfusion purpura can be prevented by selecting compatible platelets, which is often difficult because of the very high frequency of most of the antigens involved.

Rarely thrombocytopenia is induced by platelet-specific antibodies in the donor plasma. In contrast to post-transfusion purpura, thrombocytopenia occurs immediately after the transfusion in these cases.

Alloantibodies against granulocytes

Granulocyte-reactive alloantibodies, mainly HLA class I and granulocyte-specific ones, are the main cause of febrile transfusion reactions. Typically in this reaction the temperature begins to rise sharply a few hours after the transfusion which is often accompanied by chills. The temperature begins to decline after about 8 h. The reactions are due to antibody-antigen complexes liberated after the destruction of leukocytes. These complexes bind to and activate monocytes, which, after a delay, release cytokines with pyrogenic properties. These reactions can be prevented by removing most of the leukocytes from red cell and platelet concentrates, e.g. by filtration.

A much more serious reaction, transfusion-related acute lung injury (TRALI) is characterized by chills, fever, a nonproductive cough, dyspnea, and infiltration and edema of, particularly, the lower lung fields. The reaction, which may be fatal, is nearly always due to the presence of leukocyte antibodies in the donor plasma, although rarely it has been caused by antibodies in the recipient. Donors whose blood induced the TRALI should be removed from the donor panel.

Febrile reactions induced by cytokines in the transfused blood

Febrile reactions may be caused by cytokines derived from leukocytes, which accumulate due to active synthesis by leukocytes in platelet concentrates during storage. There is a correlation between the frequency of febrile reactions and the number of leukocytes in the platelet concentrate and the time of storage. Pre-storage removal of leukocytes from the platelet concentrate prevents these reactions.

Antibodies against plasma proteins

Most important are antibodies against IgA, which mainly occur in IgA-deficient subjects. Most of the antibodies are directed against nonpolymorphic epitopes on the $\alpha 1$ or $\alpha 2$ chains but anti-allotypic (A2m) antibodies may also occur. The interaction of these antibodies with donor IgA, even if very small quantities are transfused, can cause a severe anaphylactic reaction which may be fatal. Patients with such antibodies can be transfused with red cells which have been washed six times. For other blood components it is necessary to select IgA-deficient donors. Also, A2m antibodies may occur in poly-transfused patients. The reaction caused by them is much less severe, urticaria usually being the only symptom. The extent to which antibodies against other plasma proteins may cause transfusion reactions is controversial.

IgE Antibodies against nonhuman antigens

In patients who are allergic to an allergen, an allergic reaction occurs if the donor plasma contains the allergen. This may particularly occur if it concerns food allergens, which may be present in the donor plasma after consumption of the food involved. The patient develops urticaria. The reactions can be prevented, in the case of red cell concentrates, by washing the cells three times. Very rarely a similar reaction is induced by donor IgE antibodies against an allergen which at the time of the transfusion is present in the patient.

B LYMPHOCYTE ACTIVATION

Hajime Karasuyama and **Kiyoshi Takatsu**, Department of Immunology, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan

B lymphocytes, precursors of antibody-secreting cells, originate from pluripotent hematopoietic stem cells and differentiate in the fetal liver and, in adult life, principally in the bone marrow. During differentiation the diversity of antigen specificity among B cells is generated in an antigen-independent manner through the rearrangement of gene segments encoding parts of the variable region of the B cell receptor (BCR) for antigen, that is, immunoglobulin (Ig). The newly generated, surface Ig-expressing mature B cells leave the bone marrow and circulate into peripheral lymphoid organs in which they can be activated to proliferate and to differentiate into antibody-secreting cells by encounter with antigens that bear epitopes complementary to their surface Ig.

B cell responses to antigens can be classified into T cell dependent and T cell independent. Some antigens such as bacterial polysaccharides can induce vigorous B cell stimulation independently of T cells by strong cross-linking of the BCR. In contrast, efficient B cell responses to many protein antigens need an intimate interaction of B cells with 'helper' T cells. Stimulation of BCR by antigen leads to endocytosis and degradation of the antigen captured by the BCR. Peptides derived from degraded antigen are bound to major histocompatibility complex (MHC) class II molecules and transported to the cell surface to be presented to T cells. T cells expressing a particular T cell receptor (TCR) that recognizes the peptide–MHC complex presented on the B cells then become activated. The activated T cells provide help to B cells in two forms: soluble mediators (cytokines) such as interleukin-4 (IL-4), IL-5 and IL-6, and membrane-bound stimulatory molecules including CD40 ligand.

B cell activation through BCR

The BCR is a complex with a hetero-oligomeric structure in which antigen recognition and signal transduction are compartmentalized into distinct subunits. The antigen recognition subunit of the BCR is a clonally-distributed membrane-bound Ig, a

tetrameric complex of heavy and light chains, whereas the signal transduction subunit is a disulfide-linked heterodimer composed of Ig α (CD79a), a *mb-1* gene product, and Ig β (CD79b), a *B29* gene product (Figure 1). Both Ig α and Ig β chains contain within their cytoplasmic domains a sequence motif (immunoreceptor tyrosine-based activation motif, ITAM), D/E-X7-D/E-X2-Y-X2-L/I-X7-Y-X2-L/I, which is also found in the cytoplasmic tails of the signal transducers of the TCR and of Fc receptors (Figure 2).

Stimulation of B cells through the BCR results in rapid increases in tyrosine phosphorylation on a number of proteins and induces an increase of phosphatidylinositol and mobilization of cytoplasmic free calcium. Though none of the BCR subunits contains intrinsic protein tyrosine kinase (PTK) activity, the BCR associates with two types of cytoplasmic PTKs: Src family PTKs, including Lyn, Fyn, Blk and Lck, and the more distantly related PTK, Syk (Figure 1). Activation of these PTKs through ligation of the BCR by antigen leads to the phosphorylation of the two tyrosine residues within the ITAM in Ig α and Ig β , which in turn leads to recruitment and activation of additional PTKs. The activated PTKs including Btk appear to phosphorylate numerous cellular proteins involved in intracellular signaling pathways, such as the adaptor protein Shc in the Ras pathway, phospholipase C (PLC)- γ 2, GTPase-activating protein (GAP), mitogen-activated protein kinase (MAPK), phosphoinositide 3-kinase (PI3K) and Vav as well as HS-1 (Figure 1). The tyrosine phosphorylation of PLC- γ 2 increases its activity to convert phosphatidylinositol 4,5-bisphosphate into the two second messengers, diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP3). DAG activates protein kinase C while IP3 causes Ca²⁺ release from intracellular stores (Figure 1).

The regulated signal transduction through the BCR can be achieved by coordinated actions of PTKs and protein tyrosine phosphatases (PTPs). CD45 is a transmembrane PTP expressed on hematopoietic

Figure 1 Signaling pathway of BCR.

cells and plays a critical role in B cell activation following ligation of the BCR (Figure 1). The regulation of Src family PTKs by CD45 appears to be one of the bases for requirement of CD45 in antigen-induced BCR signaling. Since Src family PTKs contain a negative regulatory tyrosine phosphorylation site at their carboxyl termini, dephosphorylation of this site by CD45 results in an increase of their kinase activity. The phosphorylated tyrosine residues within ITAM of Ig α and Ig β also appear to be substrates for CD45. The importance of CD45 in BCR signaling has been confirmed by generating CD45-deficient mice in which B cells are completely refractory to proliferation stimulated by anti-IgM antibody.

Cognate T cell help for B cell activation

The CD40 ligand (CD40L) expressed by activated T cells is a 33 kDa type II membrane glycoprotein with sequence homology to tumor necrosis factor. T cells activated through TCR ligation transiently express on their surface CD40L, which interacts with CD40 expressed on B cells to deliver signals for B cell activation and proliferation. Signaling through CD40 in combination with T cell-derived cytokines such as IL-4 and IL-5 in mice leads to B cell differentiation accompanied by antibody secretion and Ig isotype switching. The CD40–CD40L interaction is also important for other B cell functions including the formation of germinal centers and the induction of

memory B cells. The physiological significance of the CD40–CD40L interaction *in vivo* has become evident from the observation of patients with X-linked hyper-IgM syndrome, who have mutations in the gene encoding CD40L and are therefore unable to express functional CD40L on their T cells. These patients fail to produce Ig of isotypes other than IgM in response to antigen challenge and also lack germinal centers in their secondary lymphoid organs.

The cognate interaction of B and T cells triggers the engagement of many other accessory molecules on both cells, which serve to stabilize the B–T conjugation and to coordinate the responses of the interacting cells. They include B7-1 (CD80), B7-2 (CD86), CTLA-4, LFA-1 (CD11a/18), LFA-2 (CD2), LFA-3 (CD58), ICAM-1 (CD54), VCAM (CD106) and VLA-4 (CD49d/29). The B7-1/B7-2 expressed on B cells interacts with the CD28 expressed on T cells to deliver a costimulatory signal to TCR-stimulated T cells, which then become fully activated to produce cytokines. T cell-derived cytokines such as IL-2, IL-4, IL-5, IL-6, IL-10, IL-13 and interferon γ (IFN γ) have been shown to enhance B cell activation and proliferation and to be essential costimuli for subsequent B cell differentiation and Ig production.

Modulation of BCR signaling

Several antigen-independent accessory molecules play an important role in the regulation and modu-

lation of B cell activation mediated by the BCR (Figure 2). Key molecules include the CD19/CD21/CD81/Leu13 complex, CD22, CD38 and the Fc receptor Fc γ RIIB1, in addition to CD45 and CD40 discussed above.

CD19, CD21 (complement receptor 2), CD81 (TAPA-1) and Leu13 form a complex on the surface of B cells. This complex functions as a coreceptor which substantially lowers the threshold for cellular activation through the BCR. Ligation of the BCR induces the phosphorylation of tyrosine residues in the cytoplasmic tail of CD19, to which PI3K binds. The coligation of CD19 and the BCR reduces by two orders of magnitude the number of antigen receptors that must be ligated to induce B cell proliferation. Therefore, B cells that encounter antigens in the form of immune complexes containing complement components may be hyperstimulated by virtue of the coligation of the BCR and the CD19/CD21 complex. Since CD21 has been shown to also interact with CD23, antigens presented on CD23⁺ cells such as follicular dendritic cells in germinal centers may also hyperstimulate B cells. Indeed, CD19-deficient mice showed the severe impairment of B cell responses to T-dependent antigens and lacked germinal center formation.

CD38 is a 42 kDa membrane glycoprotein expressed in many cell types, including B cells, and has been shown to associate with the BCR in humans. Ligation of CD38 with specific antibodies induces a potent proliferative signal to B cells in the presence of other growth cofactors such as IL-4, IL-5 or lipopolysaccharide (LPS). Engagement of CD38 also rescues germinal center B cells from apoptosis. CD38 stimulation activates Btk tyrosine kinase, and

it has been found that CD38 signaling is abolished in *xid* mice which carry a mutation in the *btk* gene and show a global B cell abnormality.

Immune complexes consisting of antigen and IgG antibodies are potent inhibitors of B cell responses. The coligation of the BCR and Fc γ RIIB1 through immune complexes leads to abortive BCR signaling (Figure 2). It has been shown that Fc γ RIIB1, when coligated with the BCR, recruits and activates a cytosolic protein tyrosine phosphatase, SHP1, through the interaction of a phosphorylated tyrosine residue within the sequence motif (immunoreceptor tyrosine-based inhibitory motif, ITIM) in the cytoplasmic domain of Fc γ RIIB1 and the SH2 domain of SHP1. The important role of SHP1 in negative regulation of BCR signaling has been clarified by the identification of mutated SHP1 genes as causative of the systemic autoimmune and immunodeficiency syndrome observed in *motheaten* (*me*) and *motheaten viable* (*me^v*) mutant mice. These SHP1-deficient mice are characterized by hypergammaglobulinemia and the production of multiple autoantibodies besides abnormalities of other hematopoietic cells, suggesting that SHP1 normally functions as a negative regulator of BCR signaling. Though the mechanism by which SHP1 modulates signaling through BCR has not yet been fully elucidated, SHP1 appears to be involved in Fc γ RIIB1-mediated negative regulation. Inhibitory signaling mediated by Fc γ RIIB1 is deficient in *motheaten* mice, indicating that SHP1 is an effector of the negative regulation of BCR signaling.

CD22, a 135 kDa B cell restricted glycoprotein, has also the sequence motif ITIM on its cytoplasmic domain, to which SHP1 is recruited after BCR ligation (Figure 2). B cells from CD22-deficient mice

Figure 2 Negative regulation of BCR signaling.

(ITAM: immunoreceptor tyrosine-based activation motif) (ITIM: immunoreceptor tyrosine-based inhibitory motif).

show hyperresponsiveness to BCR signaling, suggesting that CD22 serves as a negative regulator of BCR signaling.

B LYMPHOCYTE ANTIGEN PROCESSING AND PRESENTATION

Nobumichi Hozumi, Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Canada

Antigen presentation by B cells: a historical view

Two different cellular populations are required for the production of antibodies, as early studies have suggested. These are thymus (T cell)- and bone marrow (B cell)-derived cells. T cells help B cells to differentiate into antibody-producing cells. *In vitro* studies have revealed that the cell populations are further subdivided. Cells from the spleen are fractionated by their ability to adhere to plastic, the adherent and nonadherent cells. The adherent cells mainly consist of macrophages, whereas the nonadherent cells are comprised of T and B cells. Further studies established that T and B cells are required for primary and secondary antibody responses, and that macrophages can also act as accessory cells involved in T cell activation.

Initially, macrophages were considered to be the critical accessory cells. Subsequent experiments established the capacity of other cells to function as accessory cells, or antigen-presenting cells (APCs). These include dendritic cells (DCs), Langerhans cells, endothelial cells, Schwann cells and Kupffer cells. The expression of major histocompatibility complex (MHC) class II molecules is essential for APCs. Therefore, it is quite logical to ask whether B cells could act as APCs, as B cells express moderately high levels of the molecule. The use of rabbit antimouse immunoglobulin (RAMIg) as an antigen demonstrated that rabbit Ig-specific T cells were able to respond to B cells and macrophages with similar efficiencies in the antibody response. Macrophages presented normal rabbit Ig (NRIg) to T cells as effectively as RAMIg; however, B cells failed to present

NR1g to T cells at the same level, suggesting that antigen-specific T–B collaboration is responsible for the efficient antigen presentation by B cells. Similar experiments were conducted using a soluble antigen, keyhole limpet hemocyanin (KLH)-specific B cells. Normal resting (small) B cells from unimmunized mice were poor APCs, whereas lipopolysaccharide (LPS)-activated B cells could present KLH to KLH-specific normal T cells. Thus, it was demonstrated that normal resting B cells from unprimed mice were poor at antigen presentation.

Studies using hapten carrier systems demonstrated that antigens are recognized by two distinct cells in order to produce a hapten-specific antibody. These experiments clearly demonstrated that B cells recognize the haptenic determinant, whereas T cells recognize the carrier determinant. Based on these results an antigen bridge model was proposed, in which B cells and T cells are bridged by native antigens (hapten carrier) bound to membrane immunoglobulin (mIg) and T cell receptor (TCR). However, two important discoveries virtually destroyed the antigen bridge model. These were: 1) MHC restriction, and 2) antigen processing. The TCR makes contact with B cells via the antigen-MHC complex, thus mIg is not required for interaction with the TCR. Only processed peptides are presented to the TCR. The antigen bridge model was challenged by utilizing antigen-specific B cell and T cell clones. These experiments clearly demonstrated that antigens bound by antigen-specific mIg molecules were presented to T cells with 1000–2000-fold greater efficiency than nonspecific presentation. The antigen taken up by the B cells is processed within acidic cellular compartments and the peptides generated bind to MHC class II molecules for presentation to the TCR. Thus, the functional role of mIg on B cells for efficient antigen presentation has been firmly established. These are *in vitro* results; the role of B cells as APCs *in vivo* remains to be determined.

Antigen presentation by B cells *in vivo*

Experiments addressing this question have been carried out using mice chronically treated from birth with anti- μ antibody (anti- μ mice), a procedure which depletes Ig⁺ B cells. These mice fail to mount a secondary T cell proliferative response following immunization with hapten carrier, but do so if injected with hapten-coupled normal splenocytes, suggesting that the presence of B cells in lymph nodes is required for T cell priming. The antigen presentation capacity of unfractionated lymph node APCs was much stronger, however, than that of unfractionated spleen APCs.

The importance of B cells to T cell priming *in vivo* was further demonstrated by inoculating purified syngeneic normal resting B cells before priming them with antigen. B cell-depleted mice primed with antigen in the presence of exogenous B cells were shown to respond to the antigen, whereas control mice without inoculation of exogenous B cells could not respond. Anti- μ -treated mice reconstituted with fluorescein isothiocyanate (FITC)-specific B cells responded markedly better to FITC-ovalbumin than to trinitrophenyl-ovalbumin. These results suggest that B cells are involved in the generation of primary T cell responses. However, several groups have presented contradictory results to these early experiments, as described below.

Investigators agree that activated B cells are able to stimulate primed T cells. However, several experiments seem to suggest that even activated B cells are poor at stimulating naive T cells compared to DCs. The activation of antigen-specific T cells requires two signaling events which must be provided by APCs. The first signaling event consists of a cognate APC–T interaction between TCR and antigen peptide/MHC class II molecules. The second signal is provided by an interaction between costimulatory signaling molecules such as B7 molecules (B7-1 and B7-2) on APCs and CD28/CTLA-4 expressed on T cells. Deficiency in the second signaling in the APC–T interaction is thought to result in T cell tolerance. It has been demonstrated that B cells expressing high levels of CTLA-4/CD28 ligand fail to provide T cell-stimulating signals as strong as DCs. It is still possible that as yet unidentified costimulatory molecules are involved in this interaction. The form in which antigens are introduced into animals may additionally play a role in T cell activation. Transgenic mice expressing I-E molecules in different cell populations (i.e. B cells or DCs) were utilized to investigate the effect of different forms of antigen (peptide versus native protein). Peptide antigens are more efficiently presented to T cells by DCs. However, DCs show poor activity for the presentation of native protein antigens. In contrast, B cells are efficient APCs for protein antigens, but not peptides. Further, these experiments suggest that as little as 1% contamination of peptides in protein antigen preparations is sufficient for T cell activation by DCs. Previous experiments suggesting a poor ability of resting B cells for T cell priming should be re-examined in light of these new data.

The functional role of B cells as APCs was recently re-examined by using mice genetically lacking B cells. These mice (μ MT knockouts) were established by depleting the μ MT (membrane) region by gene targeting, which may be less abrasive than anti- μ treat-

ment. The μ MT knockouts had impaired T cell priming to protein antigens but not to peptides. Interestingly, however, KLH demonstrated an unusual ability to prime naive T cells in the B cell-depleted mice. The antigen is very potent and widely used for *in vivo* priming experiments. Investigators should pay extra attention to the experimental design when KLH is used. Antigen-specific B cells pulsed *in vivo* revealed an impressive upregulation of B7 molecules. Antigen stimulation may induce positive signaling mediated via mIg molecules; these activated B cells can then become competent APCs for the activation of naive T cells *in vivo*. Contradictory results have, however, been reported using μ MT mice. T cell responses to several antigens including not only KLH, but also H-Y (male antigen), MHC and *Shistosoma mansoni* eggs have been described. However, antigens such as H-Y and MHC are expressed on the membrane surface of APCs. Concentration of these antigens by mIg molecules and subsequent internalization are not required for presentation. One can speculate, therefore, that this critical step in B cell activation is not required for presentation of these antigens. The functional role of B cells as APCs *in vivo* has yet to be firmly established; however, investigators believe B cells must be initially activated to have the capacity of APCs for T cell priming.

Processing

MHC class II molecules are transported from the endoplasmic reticulum (ER) via the Golgi to endosomal compartments as a complex with invariant chain (Ii). The Ii prevents endogenous peptides from binding to the groove of MHC class II molecules. After

removal of Ii in the acidic endosomal compartments, peptides are able to bind to the MHC groove. Peptide-loaded MHC class II molecules are then transported to the membrane surface for antigen presentation. The amino acid residues 81–104 of Ii, dubbed class II-associated invariant-chain peptides (CLIP), remain bound to the class II antigen-binding grooves. In endosomal compartments, MHC class II-like DM molecules promote the dissociation of CLIP from the MHC class II complex. Because cells can utilize a different mechanism for antigen presentation from other APCs, namely mIg-mediated antigen internalization, the antigen peptide loading of MHC class II in B lymphocytes is expected to take place in a compartment accessible to mIg. The process may occur in early and late endosomes and lysosomes. However, investigators have found compartments which are distinct from the conventional vesicles described above. These compartments for peptide loading (CPLs) meet several requirements for antigen loading vesicles in B cells (Figure 1). mIgG and mIgM efficiently enter the compartments, and transiently accumulated MHC class II molecules are evident. MHC class II molecules in these compartments are not associated with the Ii chain. Some of the MHC class II molecules are loaded with antigen peptides. Most newly synthesized MHC class II molecules are transported through CPLs on their way to the plasma membrane. These compartments are not accessible to the transferrin receptor. Morphologically, these compartments in B cells demonstrate a physical structure with an internal vesicle membrane similar to that seen in the multivesicular bodies, an intermediate in the conventional endosomal pathway. Antigen-presenting B cells may therefore be

Figure 1 Antigen processing and presentation in B lymphocytes.

able to selectively target internalized antigen and increase the efficiency of antigen presentation by utilizing the CPL-mediated pathway.

B LYMPHOCYTE DIFFERENTIATION

John H Kehrl, Laboratory of Immunoregulation, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland, USA

B cell differentiation broadly construed encompasses both the generation of B lymphocytes from precursor or stem cells (i.e. B cell development), as well as their maturation into plasma or memory cells. B cell lymphopoiesis begins in the embryonic yolk sac, switches to the fetal liver, and shortly after birth becomes established in the bone marrow. While B-2 (conventional) B cells are continuously generated in the adult bone marrow, B-1 (CD5⁺) B cells are predominantly produced early in ontogeny in the fetal liver. Early B cell differentiation has been divided into steps or stages based on the status of immunoglobulin gene rearrangements, the expression of cell surface molecules, and the *in vitro* growth requirements of the developing B cells. One commonly used scheme based on the expression of the cell surface markers B220, CD43, BP-1 and HSA is shown in Table 1. Included in the table are the expression

levels of other important B cell markers along with the status of immunoglobulin gene rearrangements in the cells at various stages.

As B cell progenitors mature, they pass through checkpoints that assess the status of their antigen receptors (see below). Those developing B cells that fail to pass die by apoptosis. Having acquired a mature phenotype, B cells enter the secondary lymphoid tissues such as spleen or lymph nodes, where they may encounter foreign antigens. Depending upon the type of antigen and the accompanying signals the B cells receive, they enter one of several different differentiation pathways that lead to the generation of plasma and/or memory B cells. B cell differentiation is a hazardous duty and relatively few cells pass all the checkpoints.

antigen receptors of defined specificity, have greatly deepened our understanding of the molecular and biologic processes involved in B cell differentiation. Because of the importance of these experiments they will be referred to when appropriate and the phenotypes of mice that have had molecules important in B cell differentiation altered by gene targeting have been summarized in Table 2. While there are some minor differences between human and mouse B cell differentiation, the overall scheme is remarkably similar.

Early B cell differentiation

Within the bone marrow microenvironment B cell development is divided into two main physiologic compartments. The small B220⁺, CD43⁺ population that contains many rapidly proliferating cells and the larger, but mostly resting, CD43⁻ pre-B cell compartment, which derives from CD43⁺ cells. The stromal cell-derived growth factors interleukin 7 (IL-7) and kit ligand help to maintain the proliferation of the CD43⁺ cells. The recombinase machinery necessary for immunoglobulin gene rearrangements predominantly acts on the IgH loci in the CD43⁺ compartment. The Ig rearrangements are catalyzed by a protein complex that contains two lymphoid-specific components, RAG-1 and RAG-2, that are involved in recognizing the recombination sequences and cutting the DNA. DNA joining requires the DNA-

dependent protein kinase complex. Once a B cell progenitor has successfully rearranged one heavy chain gene it terminates the rearrangement process on the other allele, a process termed allelic exclusion. Expression of μ heavy chain in conjunction with the surrogate light chains λ5 and Vpre-B results in the assembly of the pre-B cell receptor. This is a major checkpoint in B cell development. The failure to express this receptor dramatically reduces the transition of developing B from the CD43⁺ into the CD43⁻ compartment, stage C' to D. Whether the outside environment delivers a signal through the pre-B cell receptor or its simple expression provides the signal remains unclear although it is likely that the tyrosine kinase p72syk is required for signal transmission. The successful progression of a progenitor B cell into the CD43⁻ compartment results in a cessation of IgH rearrangements and the completion of light chain rearrangements. The choice of κ versus λ light chain appears to be a stochastic event which in the mouse is an approximately 10:1 preference of κ over λ. A successful κ or λ rearrangement terminates the rearrangement process and the cell expresses surface IgM with either κ or λ light chains, its antigen-binding receptor. Such a cell, termed an immature B cell, must pass additional checkpoints before entering the mature B cell pool. One of those checkpoints was revealed by the analysis of mice that lack a functional mb-1 protein. Their immature B cells fail to enter the peripheral B cell pool, implying

a checkpoint that assesses the competence of the antigen receptor. Evidence for another checkpoint at this stage came from the analysis of mice transgenically expressing an autoreactive antigen receptor.

Immature B cells in these mice are either tolerized or deleted depending upon the nature of the autoreactive antigen. However, a mechanism may have evolved to rescue autoreactive B cells from this fate.

Table 2 Gene targeting of molecules involved in murine B cell development and differentiation

Targeted gene	Phenotype
<i>Cell surface proteins</i>	
BP-1	No obvious effect on B lymphocyte development and differentiation
CD19	B cell development normal, reduced responsiveness to thymus-dependent (TD) antigen, a lack of germinal centers, and failure of B1 cell development
CD21	Normal B cell development although reduced B1 cells, decreased responsiveness to TD antigens and germinal center size, increased threshold for B cell activation
CD22	Reduced number of IgM ⁺ , IgD ⁺ cells, increased Ca ²⁺ response to sIg signaling, and decreased thymus-independent (TI) response, expanded B1 population
CD23	No obvious effect on B lymphocyte development and differentiation
CD40	Impaired isotype switching, poor TD responses, and absent germinal centers
CD45	A decreased threshold for antigen-induced signaling resulting in the accumulation of potentially autoreactive B cells
HSA	Modest inhibition of early B cell development
Ig- α tail	A small impairment in B cell development, but a marked reduction in mature B (mb-1) cells, implying a checkpoint for the expression of the antigen receptor
Ig- β	Arrest in B cell development at CD43 ⁺ stage, normal DJ joining but reduced (B29) VDJ joints
Ig κ	A limited B cell repertoire, reduced number of B cells
IgD	Normal development, delayed affinity maturation of the antibody response
IL-7R	A severe block in early B cell development, failure of CD43 ⁺ cells to expand
Invariant chain	Decreased response to TI antigens, development block at immature B cell stage
TNFR1	Required for germinal center formation in the spleen
$\lambda 5$	Impaired expansion of pro-B cells to stage D and a lack of allelic exclusion
$\mu\mu$ membrane exons	An early failure of B cell development and a lack of allelic exclusion
<i>Transcription factors</i>	
Bcl-6	Normal B cell development, failure to generate germinal centers
BSAP	A failure of B cell development with an arrest at stage B. DJ but no VDJ rearrangements
E2A	An early failure of B cell development probably occurs prior to BSAP expression as no DJ rearrangements are detected
EBF	A failure of B cell development with only very early B cell progenitors present. No Ig rearrangements
Ets-1	A marked expansion of IgM plasma cells
Ikaros	A complete lack of B cell progenitors
Oca-B	Reduction in the number of mature recirculating B cells. Poor response to TD and TI antigens, a lack of germinal center formation
Oct-2	Normal development, impaired response to LPS, and impaired Ig secretion
p50	B cell development normal, impaired response to LPS and decreased serum Ig levels and impaired switching to IgG3, IgE, and IgA
PU.1	A lack of B cell progenitors, transcription and rearrangement of Ig blocked
RelB	Normal B cell development, mild reduction in B220 ⁺ cells in spleen, no germinal center formation during TD responses
Sox-4	Partial block in B cell development, Stages A–C intact, reduced number of C' and stage D cells in the bone marrow
<i>Protein kinases</i>	
BTK	Reduction in B2 cells and a severe deficiency in B1 cells, decreased IgM and IgG3, defective response to TI-2 antigens
c-Abl	Reduction in the number of mature B cells, reduction in LPS response and Ig response following SRBC immunization
Lyn	Reduced number of recirculating B cells, elevated levels of serum IgM, presence of autoantibodies implicating lyn in establishing B cell tolerance
Syk	Markedly impaired B cell development likely due to an impaired signaling from the pre-B cell receptor, thereby preventing clonal expansion
<i>Cell survival proteins</i>	
Bcl-2	Normal B cell development, collapse of peripheral immune system by massive apoptosis
Bcl-x	Markedly impaired B cell development, absence of mature B cells
Bax	B cell hyperplasia

Table 2 Continued

Targeted gene	Phenotype
<i>Miscellaneous</i>	
Ig κ intronic	Greatly impaired VJ rearrangements, normal levels of κ expression, κ : λ enhancer ratio of 1:1 rather than 1:10
Ig κ 3' enhancer	Reduction in the number of κ -bearing B cells, reduced number of rearrangements at the κ locus
J μ	Mice cannot assemble a μ heavy chain, they lack slg μ ⁺ B cells and B cell development is blocked at large, CD43 ⁺ stage (C)
RAG-1	No Ig rearrangements and an arrest of B cell development at stage B, C
SDF-1	Failure of B cell development, reduced precursors in fetal liver and bone marrow
TdT	Lack of N-terminal additions in the adult repertoire, no obvious B cell phenotype
Vav	Normal B2 B cell development but a lack of B1 cells. Mature B cells hyporeactive to antigen signaling

They may reactivate the recombinase machinery and rearrange another light chain, generating a new antigen receptor with a different specificity, a process termed receptor editing. Finally, an immature B cell acquires IgD and passes into the periphery.

B cell differentiation in peripheral lymphoid tissues

B cell differentiation in the peripheral lymphoid tissues is predominantly antigen driven. B cell antigens can be broadly divided into thymus dependent (TD) and thymus independent (TI). TD antigens are usually soluble protein antigens that require major histocompatibility complex (MHC) class II-restricted T cell help for antibody production while TI antigens do not require such help, and are often multivalent and poorly degraded *in vivo*. Good examples of TI antigens are bacterial polysaccharides. In general, TI responses generate poor immunological memory, induce minimal germinal center formation, and trigger IgG2 secretion. The B cells responding to TI antigens have a distinct phenotype (IgM⁺, IgD⁻, CD21^{high}) and localize in the marginal zone in the spleen. The dependence upon these cells for responses to TI antigens may account for the poor responses to polysaccharide antigens seen in splenectomized individuals and human infants (the marginal zone B cells don't mature until ~2 years of age). Coupling polysaccharides to a carrier protein results in an effective infant vaccine since the conjugate triggers a TD response.

Exposure to a TD antigen triggers two pathways of B cell differentiation, the extrafollicular pathway, which leads to early antibody production, and the germinal center pathway, which leads to germinal center formation, immunological memory, and the generation of plasma cell precursors. In the spleen, the antigen-activated B cells migrate to T cell-rich zones in the periarteriolar lymphoid sheath searching for T cell help. Failure to find it likely results in sub-

sequent unresponsiveness or anergy, however, successful T-B cell collaboration produces short-lived oligoclonal proliferative foci (each derived from several B cells). Many of the B cells in these foci secrete IgM and undergo isotype switching (a DNA splicing event that exchanges IgH constant region). These events depend upon costimulatory signals, CD40 and CD40L interactions (see below), and cytokines such as IL-2, IL-4, IL-6, IL-10 and transforming growth factor β (TGF β). Some B cells migrate from these foci into primary follicles to enter the germinal center pathway. Within a primary follicle an oligoclonal expansion of B cells forms the dark zone of the germinal center. There somatic mutations are introduced into the variable regions of Ig genes that may alter the B cell antigen receptor specificity or affinity. Eventually these cells migrate into the light zone of the germinal center region where they interact with helper T cells and follicular dendritic cells that have trapped antigen localized on their surfaces. Here, B cells with high-affinity antigen receptors are selected to survive, while those that lack such receptors die or perhaps re-enter the dark zone for another round of somatic mutations. B cells that acquire an autoreactive antigen receptor are also eliminated. Rescue signals such as the engagement of CD40 (a member of the TNF α receptor family expressed on B cells) induce Bcl-x and Bcl-2, resulting in the survival of selected cells. CD40, CD40L (a member of the TNF α family expressed on activated T cells), B7-1, CD21, TNF α R and CD19 all have critical roles in germinal center formation. Individuals with the X-linked hyper-IgM syndrome underscore the importance of CD40L, as they do not express functional CD40L following T cell activation and do not form germinal centers.

Passage through the germinal center leads to the formation of memory B cells or plasma cell precursors (there are few antibody-secreting cells within the germinal center). Cytokines and CD40L influence this decision. IL-2, IL-10 and IL-6 promote differen-

tiation toward plasma cells while CD40/CD40L interactions promote memory cell formation and inhibit plasma cell generation. Cytokines also contribute to isotype switching. IL-4 enhances switching to IgE and IgG4; IL-10 toward IgG1, IgG3, and IgA; and TGF β toward IgA. While plasma cells secrete large amounts of Ig, they are short-lived cells that need to be replenished to sustain high antibody levels. Plasma cells lose their membrane Ig and many of the markers used to identify B cells although they express high levels of CD38. Memory B cells are long-lived cells that contain somatically mutated V genes and are morphologically distinct from naive B cells. They can be rapidly restimulated to generate a secondary antibody response. Together the extra follicular and germinal center pathways of B cell differentiation lead to a coordinated humoral response providing the very rapid production of low-affinity antibodies, the subsequent production of high-affinity antibodies, and the potential for a rapid amnestic response. The failure of B cell differentiation at any of the many steps may result in a crippled immune system incapable of protecting an individual against many potentially pathogenic organisms or in an autoreactive immune system capable of inflicting damage upon self tissues.

B LYMPHOCYTE REPERTOIRE

Phyllis-Jean Linton, Department of Immunology, The Scripps Research Institute, California, USA

Over the years two experimental approaches have been used to assess antigen-specific B cell populations at the clonal level. These use antigenic or polyclonal mitogenic stimulation of B cells in limiting dilution. Since polyclonal stimulation encompasses a broad range of B cell responsiveness, assays for antibody production discriminate between the various antigen reactivities. In contrast, antigen stimulation is more selective in the B cells that respond, thus enabling analyses for positive antibody production. The advent of hybridoma technology not only allowed for ease in experimental execution but also made feasible the analyses of the molecular events involved. With advances in molecular biology technology, e.g. polymerase chain reaction (PCR) and reverse transcriptase-PCR, sequences could be obtained from single cells without any form of selection.

Among the early major findings are that B cell

antigen receptors are clonally distributed, each B cell expresses a single immunoglobulin specificity and each stimulated primary B cell gives rise to a clone of antibody-forming cells (AFCs) whose antibody replicates the variable region clonotype of the antigen receptor of the original stimulated B cell. Although the primary B cell clonotype repertoire is extremely diverse, individuals of the same murine strain tend to express similar repertoires. Many studies have led to the conclusion that the B cell clonotype repertoire of a given mouse strain as well as the individual mice is highly restricted during late fetal and early neonatal development, and is acquired in a highly patterned and reproducible fashion. Among the more recent findings are the elucidation of the molecular events involved in the diversity of B cell repertoire expression, the mechanisms by which each B cell obtains a single specificity, and the mechanisms that underlie the gradual

acquisition of B cell repertoire during neonatal development.

Molecular basis for repertoire expression

Diversity in the primary B cell repertoire can be generated at three levels: 1) combinatorial association of V_H , D_{H1} and J_{H1} and of V_L and J_L gene segments; 2) junctional diversity due to imprecise joining, P- or N-nucleotide additions; and 3) combination of heavy and light chains. Given all these sources of diversity, the potential for variable region diversity in the primary B cell repertoire of mice can be estimated to be at least 10^7 – 10^8 specificities. Although antibody specificity of a given B cell is determined by the genome of that cell, random somatic events as well as evolutionarily selective forces contribute to V region expression. Among those processes that exemplify stochastic somatic events is somatic mutation. Somatic mutations can occur throughout the V region but antigen selection appears to favor those mutations leading to amino acid replacements in the hypervariable regions. The studies of Berek, Milstein, Manser, Rajewsky and Siekevitz suggest that although the process of somatic mutation which occurs during the generation of a secondary immune response is responsible for an almost limitless number of new selectable specificities, it plays no major role in the diversification of the primary B cell repertoire.

Junctional diversity appears to be less random than originally thought. This is supported by the reproducible occurrence of major clonotypes in all mice of a given strain, such as the cross-reactive idiotype (CRI) found in the A strain of mice after immunization with arsonate (ARS). In addition, junctional diversity may be greatly influenced by particular D region haplotypes.

V gene segment combinations and selection are not simply a random assortment of functional V gene elements. For example, the occurrence of predominant clonotypes, such as T15, is due to a disproportionate selection of variable region gene segments from within the V region pool. In addition, Press, Fernandez, Cancro, Denis, Fung, Kearney, Klinman and Teale have shown that repertoire expression during late fetal and early neonatal B cell development is severely restricted, representing less than 1% of the total potential repertoire of an adult individual. Repertoire expression in neonates is also reproducibly and sequentially expressed among individuals of the same strain, such that the V_H region gene segments utilized during early development are clustered toward the D proximal end of the V_{H1} gene segment

complex. Reproducible differences in repertoire are found not only in neonates versus adults but, as Zharhary, Riley and others have shown, also in aged individuals. Together these findings may be interpreted as the consequence of an evolutionarily predetermined repertoire acquisition. A V_H gene may be over-represented due to a number of possibilities, including chromosomal location, copy number and accessibility to recombinases, as well as through environmental influences such as positive or negative selection.

Environmental influences on repertoire expression

Clonal selection begins to exert its influence on the B cell at the time of surface heavy chain acquisition in B cell development. Recently, several stages of pro- and pre-B cell development have been defined and in some of these stages cell division and potentially selection may occur. Following precedents in the T cell lineage, Schwartz and Stollar have suggested that the immature μ^+/κ^- or μ^+/λ^- B cell dies if its surface μ variable region binds with high affinity to a self antigen. At the μ^+/κ^+ or μ^+/λ^+ stage of differentiation, it is possible that a B cell with a high-affinity antiself receptor could avoid deletion by undergoing a second V_L (or V_H) gene rearrangement ('receptor editing'). The ability of unmutated natural autoantibodies to bind both to autoantigens and bacterial antigens raises the possibility that, in adults, pre-B cells could be selected positively or negatively by either self antigens or microbial antigens.

The expressed B cell repertoire appears to arise from the interplay of environmental influences acting upon an extremely diverse repertoire of clonally distributed specificities that are determined by the aforementioned molecular events. The environment may up- or downregulate the pre-existing specificities. To assess the effects of environmental regulation on B cell repertoire expression, the repertoire expressed in the mature B cell population is compared to that in cells directly derived from the slg^- population of bone marrow cells because these developing B cells cannot be influenced by antigenic or anti-idiotypic mechanisms requiring slg interactions. Upon comparison, the frequency of newly generated bone marrow B cell responses to various antigens (such as BALB/c responses to 2,4-dinitrophenyl (DNP), (3-hydroxy-4-nitrophenyl) acetyl (NP), phosphorylcholine (PC), α 1,3 dextran (Dex), and influenza A/PR/8 hemagglutinin (HA)) appears to be the same as that of mature B cell responses. Importantly, examination of B cell responsiveness to HA variants revealed similar reactivity patterns in the two B cell populations.

Thus, the environment does not appear to impact upon the diversification of the primary B cell repertoire.

Similarly, environmental influences appear to play little or no role in the establishment of the predominant clonotypes or clonotype families expressed in the primary B cell repertoire, e.g. the T15⁺ clonotype in PC responses, the λ -bearing antibodies to α 1,3-Dex in Igh^a mice and the λ NP^b responses. The frequency with which these clonotypes are expressed in the spleen is entirely reflective of the frequency with which they emanate from the generative cell pool. Therefore, environmental upregulation cannot explain the occurrence of dominant clonotypes.

The major environmental influences that affect primary B cell repertoire expression are through clonotype elimination during B cell maturation. During development, B cells pass through a phase during which they are susceptible to inactivation. Although the mechanisms for the downregulation of particular clonotypes are believed to involve tolerance induction and anti-idiotypic regulation, formal proof of the latter's existence *in vivo* awaits. Nonetheless, substantive evidence exists for the downregulation of the expression of certain B cell clonotypes. Examples of downregulation include responses to antigens such as murine cytochrome *c* (cyt *c*), PC, NP and α 1,3-Dex.

Experimentally induced anti-idiotypic suppression has been shown by Kearney, Kelsoe, Kohler, Accolla, Cerny and others to affect the expression of the primary B cell repertoire. Among the more convincing data for anti-idiotypic immunoregulation is the finding by Froscher and Klinman examining the λ -bearing, α 1,3-Dex specific response. The representation of this phenotype in Igh^b mice is low compared with that in Igh^a mice, and the responsiveness in the precursor versus mature B cell pool appears normal. Interestingly, if the Igh^b sIg⁻ B cell precursors are allowed to mature and respond in an allogeneic environment, the frequency of responsiveness is significantly increased. Because of the Igh haplotype specificity of this phenomenon, the elimination of the λ -bearing, α 1,3-Dex-specific B cells in Igh^b mice is thought to be the result of naturally occurring idiotype specific downregulation.

In some of the aforementioned antigen systems, clonotype elimination during B cell development is presumed to occur by tolerance induction, although the responsible self antigen has not been definitively identified. Teale, Klinman, Metcalf, Riley, Nossal, Chiller and others have experimentally induced B cell tolerance. Recently, using immunoglobulin transgenic mice, Nemazee, Weigert, Goodnow and others have demonstrated B cell tolerance *in vivo*. The toler-

ance trigger has been demonstrated as an active process requiring metabolic energy and protein synthesis by the B cell as well as surface receptor interlinkage in the form of multivalent antigen or multivalent antigen presentation. In addition, the affinity threshold to tolerize B cells as they mature through the tolerance gauntlet is higher than that required to trigger these cells once they have fully matured. Thus, B cells whose affinity for self antigen are low may escape tolerance induction; once fully mature their affinity could be sufficient to permit triggering. This phenomenon could serve to preserve repertoire diversity but at the expense of the persistence of B cells in the primary repertoire with low affinity antiself reactivities.

Repertoire expression in B cell subpopulations

The secondary B cell repertoire can be divided into three broad categories. The first category contains those secondary responses whose predominant clonotype or clonotype families are the same as those found in the primary response (i.e. total overlap in V gene usage), although the secondary antibodies have accumulated somatic mutations. Examples of these responses include the T15 clonotype, the λ -bearing antibodies to α 1,3-Dex and to some extent the λ NP^b clonotype. In the last example, the secondary response to NP in Igh^b mice is ultimately dominated by other clonotype families. The second category includes those responses whose specificities constitute a minority of the primary response but dominate the secondary response. Examples include the response to PR8-HA and the CRI in response to ARS in strain A mice. This phenotype can be explained by the preferential selection by antigen of those somatic mutants which could increase affinity. Finally, responses to 2-phenyl-5-oxazalone (phOX) by BALB/c mice, NP by C57BL/6, horse cyt *c* and *Salmonella typhimurium* by BALB/c are examples which display almost total disparities between primary and secondary responses. One possible explanation is that secondary B cells and their progenitors express variable region gene combinations that are not used by primary B cells and their precursors.

The secondary B cell repertoire, unlike the primary B cell repertoire, appears to be highly dependent upon environmental influences for its generation and regulation. Since antigenic stimulation and continued antigen selection is necessary for the establishment of secondary B cells, the secondary repertoire of individual mice within a strain can vary considerably, as seen with responses to PR8-HA and tobacco mosaic

virus protein. Although still controversial, Linton and Klinman have shown the splenic progenitors to memory B cells to be separable from the precursors to primary AFCs. These secondary B cell progenitors are stimulated by lower affinity interactions than those that are required for stimulation of precursors to primary AFCs. Moreover, as shown by Linton and Klinman *in vitro*, and later by Nossal and Goodnow *in vivo*, the progenitors to memory B cells pass through a tolerance susceptible phase. *In toto*, secondary B cell specificity appears to be derived from a broad spectrum of potentially responsive cells which are stimulated in a much less specific fashion. These specificities can somatically mutate and continue to be selected upon positively by antigen or negatively through tolerance induction of antiself reactivities.

Another small subpopulation of murine B cells has been defined by their expression of the cell surface marker Ly-1 (CD5 in humans). Because the names applied to this subset are misleading (since CD5 clearly can be induced on 'conventional' B cells and there is a subset of cells in mice that shares many features with Ly-1 B cells (i.e. 'sister' population)), these cells are now referred to as B1 cells. The B1 cells show a variety of novel features: a novel anatomical localization (enrichment in the peritoneal cavity); early appearance in ontogeny; secretion of particular autoreactive antibodies (notably antibody to a cryptic determinant on mouse red blood cells revealed by proteolytic treatment with the enzyme bromelain (BrMRBC)); extensive capacity for self-renewal; increased frequency in autoimmune mouse strains; repetitive usage of particular germline immunoglobulin variable genes; and an apparent predisposition for unregulated growth.

Since B1 cells represent a sizable portion of neonatal splenic B cells, and fetal/neonatal-derived B cells have been shown to lack non-templated nucleotide (N) region additions found at the VDJ junctions, it was thought that all B1 cells lacked N additions. This restriction in repertoire size has been attributed to terminal deoxynucleotidyl transferase, TdT, the enzyme which adds N nucleotides and becomes active during the first week after birth. A comparison of heavy chain sequences from B1 cells isolated at different stages of development revealed some N additions in the B1 cells of the adult population. The increased N-region diversity is found in the 'sister' population of B1 cells.

Since B1 cells develop early in ontogeny, repertoire differences may, at least in part, reflect selection by different endogenous antigens. For instance, the enrichment of B1 cells with N additions in adults

may be the consequence of a selective advantage. In addition, analysis of cells responding to BrMRBC has shown that the antigen receptor is encoded by novel V_H genes (V_H11 and V_H12), and the significant increased frequency of V_H11 usage in B1 cells is largely restricted to V_H11-J_H1 rearrangements. There appears to be no general overuse of particular V genes, rather such genes are used in distinctive V_H-V_L combinations to encode selected autoreactive antibodies. Moreover, B1 cells show a preference for using J_H1 gene segments which is not observed in the conventional B cell population, and while most murine pre-B and B cells preferentially use the DSP and DFL D_H gene segments in a given reading frame (RF1), cells in the 'sister' population frequently express D_H genes in another reading frame (RF2).

B LYMPHOCYTES

B David Stollar, Tufts University School of Medicine, Boston, Massachusetts, USA

B lymphocytes are the antibody-forming cells of the immune system. B cells were so named in 1965, when they were shown to develop in the bursa of Fabricius (an outpouching of the gut) of chickens and were distinguished from T cells, which develop in the thymus. Physical separation allowed identification of separate functions of B cells (antibody production) and T cells (cell-mediated responses and regulatory processes). Mammals do not have a bursa of Fabricius, but their B cells arise in the bone marrow, so the original initial-based name is still applicable.

B lymphocytes are found in blood, lymph nodes, spleen and tonsil and other mucosal tissues. About 5–25% of all human blood lymphocytes, which number 1000–2000 cells mm³, are B lymphocytes. B cells comprise a majority of the bone marrow lymphocytes, one-third to one-half of lymph node and spleen lymphocytes, but less than 1% of those in thymus. Nonactivated B cells circulate through lymph nodes and spleen, in which they are clustered in follicles and marginal zones around the follicles. Circulating B cells may interact with and be activated by T cells at extrafollicular sites, where T cells occur around small blood vessels in association with antigen-presenting dendritic cells. Appropriately activated B cells enter the follicles, where they proliferate and displace resting cells, forming germinal centers. There they differentiate into plasma cells specialized for antibody production and long-lived memory B cells.

Each B cell produces many copies of its unique antibody molecule, which it may anchor on its cell membrane or secrete into tissue fluid and blood. The membrane antibodies form a major part of antigen-binding receptors, which may initiate cell proliferation and antibody production or processing of antigen for presentation to T cells. Secreted antibodies bind antigen in blood or tissues and initiate reactions that lead to elimination of antigen from the body. Thus B lymphocytes function both in afferent and effector phases of antibody-producing immune responses.

Intracellular features of B cells

A defining feature of B lymphocytes is that they are the only cells that rearrange chromosomal DNA in the loci that code for antibodies (immunoglobulins). Other intracellular features help to identify B cells

but are not as exclusively characteristic as is gene rearrangement. Proteins associated with the rearrangement include the RAG-1 and RAG-2 recombination proteins and the enzyme terminal deoxynucleotidyl transferase (TdT). Proteins related to immunoglobulin gene expression include the transcription factors Oct-2, dimeric E2A, Bob-1 and Pu.1. Certain protein kinases that mediate signals from the antigen receptor are also characteristic of B cells.

Cell surface features of B cells

The unique B cell surface feature is the antigen receptor, formed in part by membrane immunoglobulin. Receptor assemblies of newly formed mature B cells contain immunoglobulin M (IgM) and/or IgD. B cells appropriately stimulated by interaction with T helper cells and their interleukin products may switch to production of other Ig classes, and the B cell antigen receptors then contain IgG, IgA or IgE, but not IgM or IgD. The H chain of receptor immunoglobulin is anchored in the membrane, in association with proteins Ig- α (CD79a) and Ig- β (CD79b). The intracellular domains of Ig- α and Ig- β participate in generating a receptor-mediated signal within the cell, transmitted through activation of protein kinases. Lyn (Src family) and Syk (Syk/Zap70 family) are protein kinases that associate with the resting B cell receptor and, along with additional kinases, participate in B cell activation pathways.

Other B cell membrane proteins regulate the intensity of responses that follow antigen binding (Table 1). Cross-linking of a B cell-specific complement-binding assembly (proteins CD19, CD21, CD81 and Leu-13) to the antigen receptor dramatically lowers the antigen concentration required for B cell activation. CD45, a positive regulator (perhaps an initiator) of signaling, is a transmembrane protein with a cytoplasmic tail that has essential phosphatase activity. Other phosphatases (e.g. SHP-1) are attenuating, and some membrane molecules (e.g. CD22, Fc γ R) increase the effect of attenuating phosphatases.

Additional B cell surface molecules have diverse functions, serving to present processed antigen fragments and costimulatory signals to T cells, mediate adhesion between B and T cells, or as receptors for cytokines produced by T cells (Table 2). B cell activation and class switching can be stimulated through

Table 1 B cell receptors and associated membrane proteins

<i>Receptor complex</i>	<i>Protein</i>	<i>Family</i>	<i>Function</i>
B cell antigen receptor (BCR)	IgM, IgD, IgG, IgA or IgE	Ig	Receptor-mediated signaling
	Ig- α (CD79a)	Ig	Receptor-mediated signaling
	Ig- β , Ig- γ (CD79b)	Ig	Receptor-mediated signaling
Pre-B cell receptor	Ig- μ H chain	Ig	Signaling for maturation progression
	Vpre-B	Ig	Component of surrogate L chain
	14.1 (human) λ 5 (mouse)	Ig Ig	Component of surrogate L chain
Complement receptor complex	CD19	Ig	Costimulates BCR signaling when cross-linked to BCR. Forms a complex with CD21, TAPA-1 and Leu-13
	CD21	Selectin, C-R	EBV receptor gp350/220; complement receptor, binds iC3b, CD23, IFN α
	TAPA-1 (CD81) Leu-13	Tetraspan 16 kDa membrane protein	
Modulators of receptor signaling	CD45	Tyr phosphatase	Increases BCR signaling
	CD22 (CR2)	Ig	Inhibits BCR signaling; mediates adhesion; binds to SHP-1, Syk, PLC γ 1
	Fc γ RII	Ig	Low-affinity IgG receptor
	CD23	Lectin	Inhibits BCR signaling Low-affinity Fc ϵ R2; regulates IgE production

B cell CD40, a receptor for a ligand, CD40L (also called gp39), produced by T cells. B cell apoptosis follows engagement of the cell surface protein Fas (CD95) by specific Fas ligand, which is produced by activated T cells, dendritic cells and cells of many tissues in which apoptosis occurs. Some of these surface proteins, such as CD19, are nearly unique to B cells; others, such as major histocompatibility complex (MHC) class II molecules and Fas, occur on cells of several tissues.

B cell development

B cells are generated from hematopoietic stem cells. In birds, new B cells are produced in the bursa of Fabricius in both embryonic and adult life. In mammals, B lymphocytes are produced mainly in liver and spleen in fetal life, but in bone marrow after birth. Multipotential hematopoietic stem cells can develop into lymphoid cells or myeloid cells (granulocytes, erythrocytes and platelets). Along the lymphocyte differentiation pathway there is an intermediate lymphoid precursor for both B and T cells. The earliest precursors committed only to B cell development, pro-B cells, have not yet rearranged their V region genes, but can be identified by their

ability to grow in culture in the presence of bone marrow stromal cells, kit-ligand and IL-7; their cell surface CD19 and CD43; and their intracellular terminal deoxynucleotidyl transferase, RAG-1 and RAG-2. Somewhat more differentiated (pre-B I) cells have begun to rearrange H chain V region genes but do not synthesize H chain protein. When rearrangement of H chain but not L chain gene segments is completed, developing cells synthesize and express μ H chain on the cell surface in association with a surrogate L chain (Table 1). Membrane expression of this complex is essential for progression from the pre-B I to the pre-B II stage, at which L chain rearrangement begins. L chain synthesis and Ig assembly occur in immature B cells. The unmodified term 'B cell' is applied to small lymphocytes that have completed V gene rearrangements, synthesize both chains and express cell surface Ig. Most B cells express only one rearranged H and one L chain; this process, known as allelic exclusion, ensures that a B cell will make only one antibody. The progressive stages of V gene rearrangement are accompanied by characteristic expression of cell surface proteins that are also used as markers of these stages.

At birth, before exposure to foreign antigens, new IgM⁺IgD⁺ B cells comprise a 'primary repertoire' of

Table 2 B cell membrane proteins that interact with T lymphocytes and cytokines produced by T lymphocytes

<i>B cell protein</i>	<i>Nature/family</i>	<i>Interacting T cell surface molecule</i>	<i>Function</i>
MHC class II	Ig	TCR, CD4	Presentation of processed antigen to TCR
B7-1 (CD80) and B7-2 (CD86)	Ig Ig	CD28, CTL4	Costimulatory signal in antigen presentation to TCR
CD40	TNFR	CD40L (gp39)	Germinal follicle formation, class switching
ICAM-1	Ig	LFA-1	Adhesion
LFA-1	Integrin	ICAM-1	Adhesion
LFA-3	Ig	CD2	Adhesion
Fas (CD95)	TNFR	FasL	Apoptosis signal
		<i>Soluble T cell product</i>	<i>Effect on B cells</i>
IL-2R	HCR type I	IL-2	Growth, activation, Ig secretion
TNF α R	TNFR family	TNF α	Costimulation of proliferation, Ig secretion
IFN γ R	HCR type II	IFN γ	Class switch to IgG2a; enhanced MHC class II expression
IL-4R	HCR type I	IL-4	Class switch to IgE, IgG1; stimulation of MHC class II and CD23 expression
IL-5R	HCR type I	IL-5	Enhanced growth, differentiation, Ig secretion by activated B cells
IL-6R	HCR type I	IL-6	Growth, differentiation, Ig secretion
IL-10R	Related to IFN receptors	IL-10	Increased MHC class II expression (mouse); proliferation, differentiation, Ig secretion (human)
TGF β R	Protein kinase	TGF β	Inhibition of growth; class switch to IgA, IgG2b

HCR, hematopoietic cytokine receptor; ICAM, intercellular adhesion molecule; IFN, interferon; Ig, immunoglobulin; IL, interleukin; LFA, leukocyte function antigen; MHC, major histocompatibility complex; TCR, T cell receptor; TGF, transforming growth factor; TNF, tumor necrosis factor.

cells producing diverse Ig products. Diversity of the primary repertoire is generated in various ways: rearrangement of numerous Ig V gene segments without somatic mutations (fetal mice); similar rearrangements plus the addition of untemplated nucleotides at the junction of H gene segments (humans, post-natal mice); gene conversion with a smaller number of functional genes (rabbit, chicken); or mutation of functional genes (sheep ileal Peyer's patches). By the time the B cells emerge from the bursa or bone marrow, or shortly thereafter, the great potential diversity has been narrowed by elimination of cells making strongly autoreactive antibodies and by the short lifespan of cells that encounter no antigen. About 1.5×10^7 B cells are produced in adult mouse bone

marrow daily; 10–15% of them survive to enter the total B cell pool, which totals about 5×10^8 cells. A significant fraction of neonatal IgM reacts both with bacterial antigens and, weakly, with autoantigens, as do IgM products of newly formed B cells through adult life. Normal regulatory processes, however, prevent the expansion of B cells that would produce large amounts of high-affinity autoantibodies of other Ig classes. When that regulation fails, autoantibody production is often associated with autoimmune disease.

In humans and mice a small subset of B cells expresses CD5 (Ly-1), a protein present on all T cells. CD5⁺ B cells are prominent in fetal and neonatal mice, in the peritoneum of adult mice, and

among human fetal B cells and adult B cells that make natural autoantibodies. CD5 expression may be a reflection of how antigen stimulation occurs or a marker for a particular B cell lineage.

B cell activation

When activated by either T-independent antigens or by interactions with T helper cells, small resting B cells are converted to large lymphoblasts and then either to plasma cells, specialized for antibody production, or long-lasting small memory cells. Within germinal centers, B cells are converted to large replicating centroblasts and then to nonreplicating centrocytes. Additional intermediate stages in the activation process are defined by cell surface protein expression and localization within the germinal center. Striking features of the germinal center activation process are the generation of frequent mutations in the Ig V regions and the switch from IgM to IgG, IgA or IgE production. Mutation greatly increases the diversity of antigen-binding sites. If mutation eliminates antigen binding, the cell has a short life, dying by apoptosis. The few cells in which mutation yields an Ig product with high affinity for the antigen are selected for survival. Antigen-selected cells may differentiate terminally into plasma cells, which then secrete a large amount of the antibody, or into small, long-lived, memory B cells that are distributed in blood and lymphoid tissues. These cells no longer express surface IgD.

B cell deficiency diseases

The physiological importance of B cell function is revealed by diseases that result from selective B cell deficiencies and consequent lack of antibodies (agammaglobulinemia). Bruton's agammaglobulinemia (XLA) is an X-linked defect in B cell maturation in humans, with arrest at the Pre-B I stage and a resulting deficiency in all immunoglobulin classes. A corresponding B cell maturation defect, the Xid mutation, also occurs in CBA/N mice. In male children with XLA, the maturation block results from deficiency of a B cell-specific protein tyrosine kinase, *btk*. With a profound lack of mature B cells but normal T cells, these children are particularly susceptible to infections by bacteria, mycoplasma, hepatitis virus and enteroviruses. They have recurrent middle ear infection, pneumonia, sinusitis and tonsillitis caused by *Pneumococcus*, *Streptococcus* and *Hemophilus*. Problems with infection begin several months after birth, when the pool of protective maternal antibody decreases. XLA children are not unusually susceptible to most virus or fungal infections, for which T

cell responses provide sufficient protection. In contrast, subjects with profound defects of both B cells and T cells (severe combined immunodeficiency, SCID), are threatened by all infectious agents; they survive only in a germ-free environment unless the deficiency can be treated.

Immunodeficiency with elevated IgM but very low IgG or IgA levels results from a failure in the signaling that instructs B cells to switch from production of IgM to other classes of Ig. The signals come in part from T cells, and in most subjects the basic defect is in the T cell even though it is expressed through B cell dysfunction. An X-linked type of this disease is due to a mutation in the gene for CD40L, the T cell ligand for B cell CD40. High levels of IgM in this disease are associated with autoimmunity. A non-X-linked immunodeficiency, in which there is a selective lack of IgA-producing B cells, leads to bacterial infections primarily in the respiratory, gastrointestinal and urogenital tracts.

B cell malignancies

B cells may undergo malignant transformation at various stages of development or activation. Some human acute lymphocytic leukemia cells express features of early B cells, such as expression of TdT or only cytoplasmic H chain. Infection of mouse B cell precursors with Abelson virus generates a variety of leukemic B cells frozen in development at the pre-B cell stage. Epstein-Barr virus (EBV) activates human B cells to become lymphoblasts and, occasionally, to undergo transformation to malignancy. Mature B cells occur in some acute lymphocytic leukemias and in B cell lymphomas, hairy cell leukemia, and chronic lymphocytic leukemia. Some leukemic B cells produce IgM with properties of natural autoantibodies.

Multiple myeloma is a malignant clonal expansion of a differentiated plasma cell, with production of a large amount of a single Ig molecule or Ig chain (myeloma protein). Some spontaneous myeloma proteins have identifiable antigen-binding activity, and analyses of myeloma proteins provided important keys to understanding antibody structure. Mutated myeloma cells of mice also serve as partners for fusion with specific antibody-producing cells, forming hybridomas that produce monoclonal antibodies. Overproducing cells that lack malignant properties but yield a large amount of Ig product occur in Waldenström's macroglobulinemia and primary amyloidosis.

β_2 -MICROGLOBULIN

Rho H Seong, Institute for Molecular Biology and Genetics and Department of Molecular Biology, Seoul National University, Seoul, Korea

Jane R Parnes, Division of Immunology and Rheumatology, Department of Medicine, Stanford University Medical Center, Stanford, California, USA

β_2 -Microglobulin (β_2 M) is a protein of approximately 12 kDa and is found in serum and on the surface of most mammalian cells. It was first isolated from the urine of patients whose renal tubules were damaged by chronic cadmium poisoning. The protein is referred to as β_2 -microglobulin because of its low molecular weight and its localization in the β_2 region of globulins when blood plasma is subject to moving-boundary electrophoresis.

β_2 M is noncovalently associated with several transmembrane proteins, including the heavy chain of class I major histocompatibility complex (MHC) proteins encoded by the mouse H-2 K, D and L and Qa/Tla loci and the human HLA-A, -B, and -C loci. β_2 M is also found in noncovalent association with an immunoglobulin G (IgG) receptor (Fc receptor) of neonatal gut cells and with CD1 glycoproteins. β_2 M is encoded by a single gene on human chromosome 15 and mouse chromosome 2.

Biochemical nature and evolution

β_2 M consists of a single, nonglycosylated, 99 amino acid polypeptide chain. Homologs of β_2 M have been described and sequenced for a number of mammalian species. Comparison of amino acid sequences indicates a high degree of evolutionary conservation of this protein. The overall sequence identity among the various mammalian β_2 Ms is approximately 70%, except for mouse and rat β_2 M, which, as might be expected, show greater identity (86%). The high degree of structural conservation of β_2 M among species is further indicated by the observation that β_2 M of different species can functionally substitute for each other. Since β_2 M is located entirely outside the cell with no direct attachment to the cell membrane, and since the association between β_2 M and the class I heavy chain is noncovalent, β_2 M on the cell surface can exchange with free β_2 M present in serum used to grow cultured cells. Mammalian β_2 M

contains two cysteine residues at positions 25 and 80, and these are involved in a disulfide bond. Because of sequence similarity of β_2 M to Ig molecules and because of the presence of a disulfide loop with a predicted tertiary structure similar to that of Ig domains, β_2 M has been considered a member of the Ig gene superfamily. The primary structural identity between β_2 M and the Ig constant region domain is about 30%. The similarity between them is more significant considering matches of specific key amino acids. The placement of β_2 M in the Ig gene superfamily has been confirmed by crystal structure studies discussed below. The heavy chain of class I MHC proteins is also a member of Ig superfamily.

Polymorphism

Within a species β_2 M is virtually invariant. Although a few variants have been found in many species, only in the mouse could the difference be attributed to a change in an encoded amino acid. In guinea pig, the structural difference between two variants has been shown to involve the presence or absence of a lysine residue at the C-terminus of the molecule, and it is postulated that this variation results from post-translational modification, but not from genetic polymorphism. Three alleles of β_2 M have been defined among laboratory strains of mice. Amino acid sequence analysis of the β_2 M protein obtained from Balb/c (β_2 M^a) and C57BL/6 (β_2 M^b) mouse strains revealed a substitution of aspartic acid for alanine at position 85 as the only difference between the two forms. A third variant has been identified by sequence analysis of cDNA from the mouse strain B10.pa-H-3^a/Sn. All three alleles among laboratory strains differ by a single base substitution at exactly the same base position: the second nucleotide of codon 85. β_2 M^a (e.g. Balb/c) has GCC (alanine), β_2 M^b (C57BL/6) GAC (aspartic acid) and β_2 M^c (B10.pa-H-3^a/Sn) GTC (valine).

Structure of β_2 M

Primary sequence comparisons and physicochemical data suggested that β_2 M strongly resembles Ig constant domains in polypeptide chain folding and overall tertiary structure. The structure of β_2 M in the class I heterodimeric protein was also shown to be very similar to that determined for the free β_2 M monomer from bovine serum. The crystal structure of the human class I MHC protein HLA-A2 was determined, and these data confirmed the expectation that β_2 M is very similar in tertiary structure to the $\alpha 3$ domain of class I heavy chains and to Ig

constant domains (Figure 1). Both the $\alpha 3$ and β_2 M domains in the class I MHC molecule are β -sandwich structures composed of two antiparallel β -pleated sheets, one with four β strands and one with three β strands, connected by a disulfide bond. The residues in contact across the $\alpha 3$ - β_2 M interface are in the four-stranded β sheets. The crystal structure also shows how β_2 M binds to the heavy chain of class I protein; β_2 M is positioned upward apparently supporting the $\alpha 1/\alpha 2$ peptide-binding platform (Figure 1A). This interaction results in minimal contact between the heavy chain $\alpha 3$ domain and $\alpha 1/\alpha 2$ domains, while β_2 M contacts all three domains of the heavy chain. The interaction between β_2 M and the $\alpha 1/\alpha 2$ domains extends across the entire β -pleated platform and one long stretch of β_2 M fits into a pleat on the underside of the $\alpha 1/\alpha 2$ β -pleated sheet (Figure 1C). These interactions appear to stabilize the $\alpha 1/\alpha 2$ conformation and therefore the peptide binding site on the class I protein.

Expression of β_2 M

Mouse β_2 M is encoded by a single gene per haploid genome, indicating that the same β_2 M gene encodes the light chain of the various class I proteins, CD1 and intestinal Fc receptors. The β_2 M gene consists of four exons, with the majority of the protein-coding sequence (amino acids 3–95), within a single exon (exon II). All types of interferon (IFN) (α , β and γ), of which IFN γ is usually the most potent, and tumor necrosis factor α (TNF α) have been shown to induce or increase expression of both chains of class I molecules in a wide variety of cell types. For β_2 M this is thought to occur by both transcriptional and post-transcriptional events. The expression of the β_2 M gene has been thought to be related to that of the class I heavy chain by sharing common regulatory mechanisms. However, the expression of these genes follows a different time course during embryogenesis; the synthesis of β_2 M is first detectable at the two-cell stage, while class I heavy chain mRNA is detectable after the midsomite stage on gestation day 9 in the mouse embryo. This suggests that expression of these genes is not always coordinately regulated. It has been shown in some embryonic carcinoma cell lines that expression of class I MHC proteins can be induced by driving the cells from an undifferentiated state to a differentiated state, and that transcription of both the β_2 M and class I heavy chain genes is activated by this induction. A transcriptional enhancer activity has been found in the 5' flanking sequence of the mouse β_2 M gene. This enhancer may have at least two important regions, one of which shows sequence similarity to the H-2 enhancer (class I regu-

Figure 1 The residues forming the domain interfaces are highlighted in color on the C α backbone stereogram. Filled and colored C α atoms make contacts ≤ 4 Å. latory element, CRE) region 1. Both this β_2 M sequence and region I of the H-2 enhancer bind the nuclear factors KBF1 and H2TF1.

Function of β_2 M

Although the precise role of β_2 M is not known, a number of studies suggest possible roles for it. It serves to stabilize the tertiary structure of class I heavy chains. Circular dichroism studies show that isolated heavy chains lose some of their β -pleated structure and assume more of a random coil configuration in the absence of β_2 M. Other studies have shown that when β_2 M is dissociated from the HLA heavy chain, HLA alloantisera are less able to recognize the protein, and antigenic activity can be restored if the heavy chain- β_2 M complex is carefully renatured. Cytoplasmic HLA molecules lack β_2 M in Daudi cells and are not recognized by alloantisera, but can be recognized by xenoantisera raised against denatured HLA heavy chains. In addition to stabiliz-

ing the tertiary structure of class I heavy chains, β_2 M seems to be required for the expression of these chains on the cell surface. This conclusion has been based on studies of the human Daudi cell line and of mutants of the mouse R1 cell line. In both systems mutations in the β_2 M gene are accompanied by lack of expression of β_2 M protein and lack of cell surface class I molecules. Cell surface expression of class I proteins was shown to be restored in each of these mutant cell lines after fusion to cells that express normal β_2 M protein. Furthermore, transfection of the β_2 M gene into these cell lines rescued cell surface expression of class I proteins. It has been shown that peptide binding is also required for the cell surface expression of class I proteins. Using a mutant cell line deficient in β_2 M which transports low amounts of nonpeptide-associated heavy chains to the cell surface, it has also been shown that only after association with β_2 M could heavy chain stably bind peptide. An approach using purified class I proteins also strongly suggested that peptide binding to yield

active antigenic class I MHC complexes can occur after β_2 M binding to heavy chain occurred. Thus, β_2 M association with the class I heavy chain is required for optimal peptide ligand binding to form the antigenic complex recognized by T cells. β_2 M-deficient mice were produced by disrupting the β_2 M gene by homologous recombination. In these mice, cell surface expression and function of the entire array of class I molecules were eliminated. Neonatal β_2 M-deficient mice also lacked the intestinal cell transepithelial transport of IgG from mother's milk by the β_2 M-associated Fc receptor, suggesting that the Fc receptor heavy chain in mouse must associate with β_2 M for functional expression on the cell surface. Furthermore, most CD4⁺CD8⁺ cytotoxic T cells failed to develop in these mice because of the lack of cell surface class I MHC proteins. Interestingly, the fact that these mice were born and appeared normal (except for the cellular alterations mentioned above and their consequences) demonstrates that no β_2 M-associated proteins are critical during mouse development.

bm MUTANTS

Roger W Melvold, Department of Microbiology–Immunology, Northwestern University Medical School, Chicago, Illinois, USA

Background

The H-2 complex (the major histocompatibility complex of the mouse) consists of a series of genes which are intimately involved in regulation of many functions of the immune system. Of particular relevance here are the class I and class II genes within the H-2 complex. The products of these highly polymorphic genes are particularly crucial to the various activities carried out by lymphocytes, particularly T lymphocytes. Mutations of these loci have been extremely

useful in dissecting the relationships between the fine structure and function of these genes/gene products. H-2 gene mutations have been recovered from many different genetic strains of mice, but the best known and most widely utilized have been those which occurred in the *H-2^b* haplotype (the set of H-2 genes found in strains such as C57BL/6 and C57BL/10). The mutants were typically identified because they resulted in unexpected graft rejections between animals presumed to be genetically identical, and therefore expected to be completely histocompatible.

H-2 mutants are designated by the letter of the haplotype from which they were derived (in this case, 'b'), the letter 'm' (for 'mutant') and an arabic numeral which designates the chronological sequence in which the mutants were found – thus the mutations of *H-2^b* are collectively known as the '*bm*' mutants. Prior to recent methods developed for site-directed mutagenesis, exon shuffling and transgene insertion, H-2 mutants provided the only available means for evaluating the effects of such small discrete changes in the class I and II genes expressed in the *H-2^b* haplotype. The current listing of mapped *bm* mutants is shown in Table 1.

Frequency and sources of *bm* mutants

The fact that *bm* mutants are more frequent than those derived from other haplotypes is not due to a more intensive screening of mice bearing *H-2^b*, but to the fact that one of its genes (*K^b*, the *H-2^b* allele at the *H-2K* locus) mutates spontaneously at the unusually high rate of approximately 2×10^{-4} per locus per gamete. As a result, over 80% of all H-2 mutants recovered are derived from the *K^b* gene.

One of the most interesting features of class I and class II H-2 genes is their high polymorphism, i.e. a large number of alleles per locus in the population, and it is assumed that this unusually high diversity is an important part of their biological role(s). The *bm* mutants display three characteristics which bear on the source of this variability: 1) the unusually high mutation rates, 1–2 orders of magnitude above those for average mammalian genes; 2) the recurrence of identical amino acid changes in several independently arising mutations; and 3) multiple (but not necessarily adjacent) amino acid changes resulting from single mutational events. It has been shown that these genes engage in exchanges of DNA sequences between homologous, but non-allelic, genes. This process (referred to as gene conversion, microconversion or microrecombination) can occur during either meiosis or mitosis, and the details of its mechanism are still unknown. Analysis of H-2 mutations derived from the *H-2^d*, *H-2^f* and *H-2^k* haplotypes indicate that these mutations can also be attributed to microrecombination, although their frequency is far below that of *K^b*.

Functional consequences of *bm* mutations

Class I H-2 molecules are crucial in directing the function of CD8⁺ cytotoxic T lymphocytes. As they progress toward the cell surface during their synthesis, they bind to peptide fragments, which they

ultimately 'display' on the cell surface. They thus present to CD8⁺ T lymphocytes a sampling of intracellular peptides, including those derived from infectious organisms growing within the cell.

The T cell receptors of each CD8⁺ T lymphocyte

are specialized so that they bind only to a specific combination of [antigen + class I molecule] on a cell surface. The amino acid sequence of the peptide-binding region(s) of a major histocompatibility complex (MHC) class I molecule imparts an affinity for preferential binding of particular peptides. Thus changes in the amino acid sequence of a class I molecule can alter the subset of peptides which are displayed on the cell surface, and this in turn determines which subset(s) of CD8⁺ T cells are able to bind and become activated. Therefore, changes in MHC class I molecules can alter the immune repertoire. The *bm* mutations, by altering only one or a few amino acids at various sites in the *H-2K* and *H-2D* gene products have been crucial in identifying which portions of these molecules are important sites for the associations between class I molecule and peptide and between class I molecule and T cell receptor. Small changes, even only a single amino acid, can completely alter the ability of some individuals to respond to particular antigens. While all of the class I *bm* mutants affect cell-mediated functions, their effects on serologic functions are somewhat less consistent and dramatic, and many of them fail to stimulate antibody production when mutant and parental mice are immunized against one another.

Only a single spontaneous *in vivo* mutation of an H-2 class II gene has been recovered, and it too is a *bm* mutant (*H-2^{bm12}*). CD4⁺ T lymphocytes recognize combinations of [peptide + class II molecule] on cell surfaces. The *bm12* mutation, which involves a change in only three amino acids, has profound

effects on the immunobiology of the mutant animal by altering the way in which the class II molecule interacts with antigenic peptide or with T cell receptors on CD4⁺ lymphocytes. For example, the mutant is unable to respond to some antigens to which the parental strain responds well. On the other hand, the mutant has gained the ability to respond to certain antigens to which the parental strain is unable to respond. The mutation is also able to confer resistance to the development of an autoimmune disease, experimental myasthenia gravis, to which the parental strain is susceptible.

In summary, the *bm* mutants have provided exquisitely subtle genetic tools for the fine-detail analysis of H-2 gene structure and the relationship of that structure to the function of the resultant gene products, and are particularly valuable where whole, intact animals are required to study a particular process. They have been instrumental in the assignment of diverse biological and immunologic functions to single H-2 genes, and have even been shown to influence mating preferences, in that mice can distinguish parental animals from those carrying *bm* mutations by urine-associated odors. The *bm* mutations, and those derived from other haplotypes as well, will undoubtedly continue to demonstrate their value in immunogenetic research.

Ontogeny

During human development hematopoiesis passes through several distinct phases. In the embryo, large megaloblastoid nucleated red cells are produced in the extraembryonic membranes, from where they enter circulation. These cells synthesize the embryonic hemoglobins Hb Gower 1, Hb Gower 2 and the relatively minor hemoglobin Hb Portland. From 6 weeks gestation, erythropoiesis transfers to the fetal liver. At this time there is a switch in Hb production from the embryonic Hbs to fetal Hb ($\alpha_2\gamma_2$). This switch is time rather than site dependent, with residual erythroid cells in the extra-amniotic membranes at this stage also producing fetal Hb. Bone marrow hematopoiesis is established between the 11th and 22nd week of gestation and probably arises by stem cell migration into appropriate marrow stroma. In mid-gestation there are high levels of circulating hematopoietic progenitor cells which decline progressively until birth. At about 40 weeks gestation the synthesis of fetal Hb is replaced by adult Hb ($\alpha_2\beta_2$) and this event is related not to birth but to the time of gestation. The Hb switching involves the serial expression of the α -like globin chains on chromosome 16 and the β -like globin chains on chromosome 11 in a 5' to 3' direction. The precise mechanism of the switch is not understood.

The fetal liver contains both myeloid and erythroid progenitor cells and yet few phagocytes are produced until the end of gestation. This indicates that in aseptic fetal life there is inadequate environmental stimulus to induce the proliferation and differentiation of myeloid progenitor cells. Around the time of birth there is a pronounced rise in the peripheral blood neutrophil and monocyte levels. Lymphocytes appear in the blood by 8 weeks gestation and by the second trimester the T cells have a mature but generally naive phenotype. Full functional competence is not gained until after birth. The fetal blood contains relatively high numbers of circulating stem and progenitor cells and although these levels fall throughout gestation, cord blood levels are still sufficiently high to allow the use of cord blood for allogeneic hematopoietic stem cell transplantation.

Stem cell origin of hematopoiesis

There is definitive evidence that multipotential stem cells give rise to cells of all the myeloid and lymphoid elements. In chronic myeloid leukemia the clonal expansion involves not only the red cell, platelet and phagocyte series but also B lymphocytes. Transplantation experiments in mice using stem cells marked by retroviral insertions indicate that T cells are also derived from a common lymphohematopoietic stem cell.

In the adult the large majority of hematopoietic stem cells are noncycling. These cells can be assessed in mice by competitive repopulation assays into irradiated recipients. The enumeration of cells capable of forming day 12 spleen colonies (CFU-S) in irradiated mice (assay developed by Till and McCulloch in the early 1960s) allows a simpler quantitation of primitive cells, but the most primitive repopulating stem cells are at an earlier stage in the developmental pathway than the average CFU-S. There is obviously no direct human equivalent of the CFU-S assay but stem cells can be grafted into immunodeficient mice, and such studies are providing important information about human stem cell biology. Assays of cells capable of forming 'cobblestone areas' on preformed stroma also provide an assessment of very primitive cells. When appropriately stimulated these cells proliferate and either undergo a process of self-renewal or differentiate ultimately to mature cells. A single stem cell can almost totally repopulate a mouse, although in the steady state a very large number of stem cells are available. The morphological appearance of the most primitive stem cells is probably similar to a small lymphocyte. As it proliferates and differentiates it assumes a blastic appearance. The majority of cell divisions arise in this blast cell pool, and the recognizable precursor cells in the bone marrow are the outcome of only the terminal six or seven divisions. As stem cells pass down the differentiation pathway, there is progressive commitment to a given lineage and the stem cell progeny lose the potential for self-renewal. The process of commitment has a stochastic (random) element but is sensitive to environmental modulation. Cells intermediate between the stem cells and the more mature precursor cells are known as progenitor cells and can be quantitated by *in vitro* colony forming assays. These assays were developed

in the murine system by Pluznik and Sachs and by Bradley and Metcalf in the mid-1960s. In these assays, immobilized suspensions of hematopoietic cells are induced to form colonies in the presence of 'colony stimulating factors'. The cells giving rise to colonies are capable of many cell divisions and may have either restricted or multiple lineage potential. They are not, however, capable of self-renewal. The colonies and cells giving rise to them are named after the mature progeny that they produce: G-CFC, M-CFC, GM-CFC, Eo-CFC and Mega-CFC give rise to granulocytes, monocytes, both granulocytes and monocytes (and also eosinophils), eosinophils and megakaryocytes, respectively. Relatively late erythroid colony forming cells are referred to as colony forming units – erythroid (CFU-E), and the early erythroid progenitor cells as burst forming units – erythroid (BFU-E) because of the multiple cluster appearance of these colonies. CFC-mix give rise to cells of multiple lineages. There is some evidence that T cells may be derived from these CFC-mix progenitors, but this has not been widely confirmed.

Myelopoiesis

Hematopoietic growth factors

Myelopoiesis is regulated at least in part by a series of glycoproteins referred to as hematopoietic growth factors (HGFs). Erythropoietin, produced in response to hypoxia by the peritubular adventitial cells of the kidney, is a true hormone, and G-CSF is similar in so far as the circulating levels are inversely related to the neutrophil count. Interleukin 6 (IL-6) levels also rise in neutropenic and infective states. Thrombopoietin, which regulates megakaryocyte production, is of particular interest as the serum levels are largely regulated by end-organ (platelet) sequestration, and more thrombopoietin becomes available when the platelet count falls. Several other HGFs such as GM-CSF and IL-3 cannot be readily measured in the plasma and probably act in a paracrine manner.

From *in vitro* and *in vivo* studies, the HGFs can be grouped into three broad categories. Firstly, there are the late-acting factors which are relatively lineage

restricted and stimulate the terminal divisions of the maturation pathway with associated differentiation to mature cells (Table 1). These include erythropoietin, G-CSF, M-CSF, Eo-CSF, known as IL-5, and thrombopoietin (TPO). The proliferation of more primitive cells in the pathway is regulated by the multi-CSFs IL-3 and GM-CSF. Both of these factors stimulate the early divisions of several cell lineages, including granulocytes, monocytes, eosinophils, megakaryocytes and red cells; IL-3 also stimulates mast cell progenitors and some early lymphoid cells. It is probably active at an earlier stage in the myeloid differentiation pathway than GM-CSF but probably has little effect on the most primitive stem cells. More primitive stem cells are influenced by a range of factors including stem cell factor (SCF), Flt-3 ligand, IL-6, IL-11, and leukemia inhibitory factor (LIF). These factors render very primitive cells susceptible to the later-acting factors and are thus often referred to as 'synergistic factors'. The categorization of the HGFs into three groups is undoubtedly an oversimplification and G-CSF and M-CSF, for instance, have some effects on primitive progenitor cells.

The most primitive of all stem cells appear not to be responsive to known soluble factors and the additional signals required for proliferation of these cells is poorly understood.

Finally, the activity of the HGFs is not restricted to immature cells. G-CSF enhances many of the functional activities of mature neutrophils; GM-CSF enhances neutrophil, monocyte and eosinophil function; and M-CSF and IL-3 prime some monocyte functions – the latter also modulating eosinophil and mast cell function.

The central importance of erythropoietin in red cell production is apparent from the profound anemia that occurs in anephric individuals. Similarly, mice with knockouts of the G-CSF or thrombopoietin genes have severe neutropenia and thrombocytopenia, respectively. Knockout mice without a functional GM-CSF gene have normal blood counts but do develop a pulmonary condition secondary to poor alveolar macrophage function, in line with the view that many of the earlier-acting factors exhibit considerable redundancy with regard to hematopoiesis and that a major role for GM-CSF is as an inflammatory mediator. The Steel mouse however, which is unable to produce SCF, develops a macrocytic anemia, mast cell deficiency and albinism which in some strains can be lethal.

Hematopoietic growth factor receptors

Each HGF has a specific receptor or receptors, these being expressed at low levels, generally in the range

Table 1 Growth factors in hematopoiesis

Stem cells		Mature myeloid cells
SCF	IL-3	Erythropoietin
Flt-3 ligand	GM-CSF	Thrombopoietin
IL-6		G-CSF
IL-11		IL-5
LIF		(M-CSF)

of 10^2 – 10^3 receptors per cell. These receptors can be considered as two categories. Firstly the M-CSFR, which is the cellular homolog of v-fms and the SCFR which is the cellular homolog of v-kit are tyrosine kinase receptors similar to the PDGF receptor. Ligand occupation causes autophosphorylation and dimerization of the receptor chains followed by a cascade of signaling events mediated largely by cytoplasmic enzymes binding to phosphorylated tyrosine residues in the intracytoplasmic domains of the receptor. The EpoR, G-CSFR, GM-CSFR, TPOR, IL-3R, IL-4R, IL-5R, IL-6R, IL-7R, IL-11R, IL-13R and IL-15R are all members of the cytokine receptor family. The EpoRs, TPORs and G-CSFRs appear to consist of a single chain which dimerizes on activation by ligand. Other members of the family appear to be composed of two components. The GM-CSFR has an α chain which binds to GM-CSF with low affinity and a β chain which, although unable to bind GM-CSF when expressed alone, when complexed to an α chain produces a high affinity GM-CSF receptor. This β chain is common to the IL-3R and the IL-5R, and is largely responsible for signal transduction, which accounts in part for the similarity of action of these factors in cells which express more than one of the relevant α chains. Other receptors are even more complex, with at least three heterologous components: α , β and γ . The receptors for IL-2, IL-4, IL-7, IL-13 and IL-15 all share a common γ chain. The cytokine receptor chains do not contain a tyrosine kinase but they are able to bind and activate members of the Janus family of tyrosine kinases (JAKs). Activation of these kinases leads to activation of a family of transcription factors known as STATS, the c-myc pathway and the ras-MAP kinase pathway. The latter pathway is also stimulated by the shc binding directly to the activated receptor with subsequent activation of ras.

Bone marrow microenvironment

The specialized environment provided by the bone marrow stromal tissue is essential for effective hematopoiesis, particularly for the survival, self-renewal and proliferation of stem cells. The microenvironment is often considered to provide a 'stem cell niche', but this terminology is not particularly illuminating and, although it is now over 15 years since Dexter and colleagues established bone marrow stromal cultures which could support stem cell and thus long-term hematopoiesis *in vitro*, a limited amount is known about the precise function of the stromal tissue. Adhesion of certain categories of stem cells to the stroma is probably essential for proliferation and it is also likely that the stroma can provide negative regulatory signals to other stem cells, helping to

maintain them in the relatively protected G_0 state. A large range of adhesion molecules has been described on primitive hematopoietic cells, including the integrins VLA-2, -4, -5 and LFA-1, members of the immunoglobulin superfamily such as ICAM-1 and -3, PECAM-1, Thy-1 and LFA-3, the selectin L-selectin, the ligands for P-selectin and L-selectin and a number of sialomucins and other ligands, including CD6, CD34, CD43 and CD44.

The bone marrow stromal cells undoubtedly produce SCF. SCF contains a highly hydrophobic region so that, unlike the other HGFs, a large amount remains cell associated rather than being secreted as a soluble factor. It is likely that there are other stromal associated factors of this type. M-CSF, IL-6 and IL-7 are also produced constitutively but it has proved difficult to show that stromal cells produce other HGFs. This may be because only very small quantities are required in the context of intimate cell-to-cell contact. Furthermore, it has been shown that components of the stromal matrix avidly bind a range of HGFs, and this may serve to present a local stimulus to a stem cell or progenitor cell without releasing HGF into the surrounding milieu.

Lymphopoiesis

Primitive hematopoietic stem cells migrate from the bone marrow to the specialized environment of the thymus which is the site of T cell development. B cells by contrast, or at least immature B cells, are produced in the bone marrow, with only the later stages of B cell maturation and selection occurring in the peripheral lymphoid tissues. The bone marrow stages of B cell development have been designated as stem cell, early pro-B cell, late pro-B cell, pre-B cell and immature B cell on the basis of sequential immunoglobulin gene rearrangements and the expression of surface immunoglobulin. The earliest B cell precursors appear to be dependent on adhesion to the bone marrow stroma and VCAM-1, VLA-4 and CD44 have been particularly implicated in B cell development. The multipotent stem cells can be regulated by a number of early-acting cytokines as discussed above, but at the late pro-B cell stage a requirement develops for the presence of IL-7, which is produced in small quantities by the stromal cells.

BORDETELLA, INFECTION AND IMMUNITY

Gwendolyn E Wood and Richard L Friedman, Department of Microbiology and Immunology, University of Arizona College of Medicine, Tucson, Arizona, USA

Bordetella pertussis is a strict human pathogen which causes the respiratory disease whooping cough or pertussis. The other *Bordetella* species (*B. parapertussis*, *B. bronchiseptica*, *B. avium* and *B. hinzii*) are primarily animal pathogens but can, at times, cause disease in humans.

It is estimated that over 60 million cases of pertussis occur worldwide each year, resulting in 700 000 deaths. Clinically, pertussis has three phases. The disease begins with the catarrhal phase which may last from 7 to 21 days and is typified by symptoms similar to a common cold. The paroxysmal phase begins with severe, violent coughing spells and an inspiratory 'whoop' typical of the disease. This intense coughing lasts 2–4 weeks and can result in cyanosis, vomiting, severe exhaustion and death in infants. During the final or convalescent phase, cough paroxysms gradually decrease over 3–4 weeks. Although pertussis is considered a childhood disease, recent studies have demonstrated a high incidence of pertussis in adults.

Characteristics of the organism and its antigens

B. pertussis is a strictly aerobic, gram-negative coccobacillus which oxidizes amino acids as energy and carbon sources. Diagnosis of pertussis involves culture of the organism from nasopharyngeal swabs on Bordet–Gengou or Regan–Lowe agar (charcoal agar) and specific identification by direct immunofluorescence. Growth of *B. pertussis* on all media (at 35–37°C) is slow, requiring 2–6 days for the appearance of tiny, pearl-like colonies.

B. pertussis produces a large number of antigens, including adhesins and toxins that play a role in disease. The bacterium adheres specifically to the ciliated respiratory epithelium and remains localized in

the airways. Attachment factors include filamentous hemagglutinin (FHA), fimbriae and pertactin (PRN). FHA is a secreted and surface-associated filament-like protein composed of numerous monomeric 220 kDa subunits which agglutinate erythrocytes from several different species *in vivo*. *B. pertussis* produces two serologically distinct fimbriae (types 2 and 3) which appear to facilitate adherence to the upper respiratory tract. PRN is a nonfimbrial, 69 kDa outer membrane protein that also plays a role in attachment. Both PRN and FHA contain the amino acid sequence Arg-Gly-Asp (RGD) that mediates attachment to mammalian cells.

B. pertussis produces several toxins including pertussis toxin (PT), adenylate cyclase toxin (ACT), tracheal cytotoxin (TCT), and dermonecrotic toxin (DNT). Pertussis toxin (PT) is the most studied and has many biological activities *in vivo* including leukocytosis, histamine sensitization, stimulation of insulin secretion, and mitogenicity. Pertussis toxin is a classic A-B type toxin. After binding a specific host cell receptor via the B subunit, the toxin is internalized, and the A subunit catalyzes the adenosine 5'-diphosphate ribosylation of a group of guanine nucleotide regulatory proteins. This leads to increased host cell adenylate cyclase activity.

Host cell cAMP levels are also increased by the action of ACT. ACT enters mammalian cells where it is activated by calmodulin and converts host ATP to cAMP. As a consequence of its ability to insert into eukaryotic membranes, ACT is also responsible for the organisms's hemolytic activity on blood-containing culture media. ACT is a member of the RTX family of bacterial toxins which have in common a series of nonameric amino acid repeats in the C-terminus of the protein.

TCT is a 1,6-anhydromuramic acid-containing disaccharide-tetrapeptide fragment of peptidoglycan

released by growing bordetellae. In humans, TCT causes extrusion of ciliated cells, increases the frequency of sparsely ciliated cells and is toxic for other cells at epithelial surfaces. These changes cause a profound disruption of mucociliary clearance, leaving coughing as the only means to clear mucus and debris from the airways.

DNT is a heat-labile toxin that produces vasoconstriction and subsequent necrosis when injected subdermally in mice. Its specific role in disease progression is not understood.

B. pertussis lipopolysaccharide (LPS) is highly immunogenic with the properties typical of an endotoxin. It has a lipid A moiety linked via keto-deoxyoctulosonic acid to a branched-chain oligosaccharide domain containing heptoses and hexoses. The role of LPS in the pathogenesis of pertussis has not been well studied. The recent cloning and sequencing of the LPS operon should allow a specific determination of its contribution to virulence.

All *B. pertussis* virulence factors (except TCT and LPS) are regulated by the BvgAS system which belongs to the two-component family of bacterial transcriptional regulators. BvgS senses changes in the environment and phosphorylates BvgA; phosphorylated BvgA then activates transcription of the virulence factor genes. While the *in vivo* signals are not known, the Bvg system can be activated *in vitro* by increasing the temperature from 25°C to 37°C or by decreasing the concentration of MgSO₄ and nicotinic acid in the culture medium. This system presumably prevents wasteful synthesis of virulence factors not needed until the organism encounters a suitable host. The Bvg⁺ phase is required for full virulence of *B. pertussis*. The Bvg⁻ phase may be important in establishment of infection, persistence, transmission and/or survival in an unidentified environmental reservoir.

Immune response of the host

Humoral and cell-mediated immune (CMI) responses to pertussis are poorly understood. Neutralizing antibodies are considered to be a major protective mechanism against infection with *B. pertussis*. Recent vaccine trials demonstrated that antibody levels to *B. pertussis* antigens including PT, FHA, PRN and fimbriae correlate with protection against pertussis. In addition, a nonlethal pertussis infection provides long-term immunity to subsequent pertussis, and recovered patients produce anti-*B. pertussis* immunoglobulin A (IgA) in serum and saliva, suggesting the importance of mucosal antibodies.

However, CMI may also be important since *B. pertussis* specific T_H1 cells are found in humans fol-

lowing vaccination or infection. In mice, high anti-*B. pertussis* IgG correlates with rapid clearance of the bacteria in a respiratory infection model but a pertussis-specific CMI response is required for complete elimination of the organisms from lungs. *B. pertussis* survives in human monocytes and other mammalian cells *in vitro*, and a CMI response may be necessary for eliminating this potential intracellular reservoir of bacteria. In humans, natural immunity induced by infection may prevent respiratory colonization whereas immunity generated by vaccination may protect against toxin-mediated disease.

Evasive strategies by the organism

Many of the antigens produced and secreted by *B. pertussis* have been demonstrated to suppress the normal responses of the host to pertussis *in vitro* and *in vivo*. TCT, by destruction of ciliated epithelial cells, impedes clearance of bacteria, mucus and debris from airways. Mucociliary clearance is an important first line of defense and its destruction predisposes the patient to the secondary bacterial infections that commonly occur in pertussis.

Both ACT and PT have been demonstrated to inhibit immune cell function via induction of increased intracellular cAMP levels. PT and ACT reduce the migratory, chemotactic and phagocytic capabilities of polymorphonuclear leukocytes, blood monocytes, alveolar macrophages and lymphocytes. A synergistic effect between ACT and PT may occur locally in the respiratory tract to suppress the immune response to the infection and allow the organism to survive and persist in the host.

Variation of fimbrial type occurs readily in pertussis infections. *B. pertussis* may produce one, both or neither type of fimbriae and this may represent a means of avoiding fimbrial type-specific immune responses.

Vaccines

A whole-cell vaccine was in extensive use by the 1950s but, while the vaccine is effective at reducing the incidence of pertussis in vaccinees, it is reactogenic, fails to confer lasting immunity and is poor at protecting infants less than 6 months old. The whole-cell vaccine is composed of killed whole virulent *B. pertussis* combined with diphtheria and tetanus toxoids (DT) in the DTP vaccine. In the USA, infants are immunized beginning at 2 months of age and given three primary injections, followed by two boosters at 4–6 years of age. The US whole-cell vaccine is efficacious when all doses are given, with 80–95% protection levels reported. However, adverse

effects including local pain, redness, swelling and fever occur in 30–70% of vaccine recipients. Inconsolable crying, excessive somnolence and febrile seizures have been reported in rare cases with no permanent neurological damage.

Concerns about adverse effects associated with the vaccine led to loss of public confidence in the vaccine and decreased use, with a resultant increase in pertussis cases. This prompted efforts to produce an acellular vaccine, which was first developed in Japan and shown to be safe and effective. Various acellular pertussis vaccines contain 2–5 purified components which may include pertussis toxoid, FHA, PRN, and fimbriae types 2 and 3. The results of initial field trials led to the approval in the US of an acellular vaccine for boosters (fourth or fifth dose) when the whole-cell preparation is used for primary immunization.

Recent studies in Sweden and Italy compared DT alone and DT combined with either acellular or whole-cell pertussis vaccines for primary immunization. In both trials, the acellular preparations produced fewer and milder side-effects than the whole-cell vaccine and were more effective at inducing serum antibody responses and protection from pertussis. In 1996, acellular pertussis vaccines were approved for use in primary immunization against pertussis by the US government.

BORRELIA, INFECTION AND IMMUNITY

Ronald F Schell and **Steven M Callister**, Department of Medical Microbiology and Immunology, University of Wisconsin Medical School, Washington, USA

Although the clinical presentation of borreliosis, especially relapsing fever, has fascinated physicians for centuries, the mainstream of immunologic research bypassed the disease for many years. The advent of penicillin and DDT discouraged researchers anxious to study the immunology of borreliosis. After World War II, except for a few devotees whose laboratories continued to work on some problems related to the microbiology and immunology of relapsing fever, research on *Borreliae* was ignored. Scientific publications plunged from 50 a year in the 1950s to approximately 10 a year in the 1980s.

The increased recognition of Lyme disease

renewed interest in the *Borreliae*. Lyme disease was first recognized in Europe during the early 1900s. However, this illness was not reported in the USA until 1969, when a grouse hunter from Wisconsin contracted the first reported case of Lyme disease in North America. Subsequently, additional cases of Lyme disease were reported from the upper Atlantic Coastal states and the upper midwest of the USA. Human cases have since become increasingly recognized throughout the world. Lyme disease is the most common tick-associated illness in the USA.

During the 1980s, the spirochetal bacterium *Borrelia burgdorferi* was implicated as the causative agent of Lyme disease. Since that time, molecular

characterization studies have demonstrated at least several *Borrelia* subsp. capable of causing Lyme disease. The three most common are *B. burgdorferi* sensu stricto, *B. afzelii* and *B. garinii*. To date, only *B. burgdorferi* sensu stricto spirochetes have been detected in the USA, while these three genospecies are found throughout Europe.

Borreliae are entirely host-associated. Spirochetes have been found only in arthropods or host vertebrates that the arthropods have fed upon. *B. burgdorferi* sensu lato spirochetes are transmitted to human hosts by ixodid ticks of the *Ixodes ricinus* complex. Lyme disease is a multisystem disorder which usually begins with localized infection of the skin manifested by an expanding skin lesion, erythema migrans (EM), and constitutional symptoms such as fatigue, headache, mild stiff neck, arthralgia, myalgia and fever. Subsequent dissemination of the spirochete can cause more severe clinical manifestations, including secondary annular skin lesions, meningitis, Bell's palsy, radiculoneuritis and atrio-ventricular heart blockage. Arthritis or nervous system manifestations are hallmarks of chronic Lyme disease. An additional late manifestation, acrodermatitis chronica atrophicans, is seen primarily in Europe. Differences among the genospecies of *B. burgdorferi* sensu lato may account for geographic and regional variations in the clinical presentations.

In contrast to Lyme disease, relapsing fever caused by *B. hermsii* confirms that this illness is primarily a result of infection in the bloodstream. The clinical presentation is characterized by periods of fever lasting several days, separated by week-long intervals of normal temperatures. Diseases caused by *Borreliae* are curable with antimicrobial agents and are rarely fatal.

Spirochetes are not closely related to either gram-negative or gram-positive bacteria. *B. burgdorferi* sensu lato spirochetes are 0.2–0.3 by 20–30 µm. These organisms are highly flexible, left-handed (rotate in counterclockwise direction) helical cells, composed of 3–10 loose coils. They are susceptible to drying, but can survive for several months in medium at 4°C. The Lyme spirochete is composed of an outer cell membrane (outer sheath), protoplasmic cylinder and numerous flagella.

Some *Borreliae* are also surrounded *in vivo* by an amorphous slime layer. The slime layer, likely composed of host components, is weakly attached to the spirochete and is lost upon washing. The presence of host proteins in the slime layer may explain the inability of humans or animals to eliminate the Lyme disease spirochete despite a vigorous immune response. Thus, the spirochete may evade direct cell killing, antibody-dependent phagocytosis or anti-

body-mediated lysis with a coating of protective 'self molecules' that prevent immune recognition.

A similar outer envelope exists on *Treponema pallidum*. Treatment of treponemes with detergents to remove this outer envelope is required to achieve high reactivity in immunologic assays. The polysaccharide 'capsular' material appears to prevent phagocytosis. Similarly, there is evidence that carbohydrates are present in the slime layer of *B. burgdorferi* sensu lato, which may also influence the destruction of spirochetes by host factors.

The outer cytoplasmic membrane of Lyme disease spirochetes has a trilaminar organization of 45–62% protein, 23–50% lipid and 3–4% carbohydrate. The fluid membrane can be easily separated from the underlying protoplasmic cylinder with dilute solutions of sodium dodecyl sulfate or nonionic detergents. The outer membrane can move to one end of the spirochete by a phenomenon called 'patching' or 'capping'. The outer envelope layers also form blebs when *B. burgdorferi* sensu lato are incubated with specific antibody and complement. Bleb formation is a prelude to cell death.

The major surface proteins are located in the outer cell membrane of *Borreliae*. To date, outer surface proteins (Osp), designated A, B, C, D, E and F, have been demonstrated in *B. burgdorferi* sensu lato organisms; however, their functions remain unknown. These proteins are heterogeneous, especially among European isolates. Initial investigations demonstrated that the Osp A of USA isolates was homogeneous; however, more recent investigations have confirmed significant heterogeneity. The genes for Osp A and Osp B are located on a 40 kb double-stranded linear plasmid. Linear plasmids also encode the variable major proteins (VMP) of *B. hermsii*, which undergo antigenic variation. These antigenic changes allow survival of spirochetes in the human host for extended periods of time. Lyme disease spirochetes also appear to upregulate or down-regulate individual Osps, especially Osp A and Osp C, during infection of humans.

A variety of other antigens can also be detected in the outer membrane of *B. burgdorferi* sensu lato. These include proteins with molecular weights of 16, 27, 55, 60, 66 and 83 kDa. Antibodies against these proteins are readily detectable in chronic and complicated cases of Lyme disease. However, their relationship to the chronic nature of the disease and development of autoimmune immunologic reactions has not been elucidated. No single or combination of polypeptides has been directly associated with the different clinical manifestations of Lyme disease. The development of persistent or chronic Lyme arthritis that is not responsive to antimicrobial therapy has

been associated with an immune response to Osp A and Osp B and class II major histocompatibility complex molecules HLA-DR4 and HLA-DR2.

The flagella, responsible for motility, are located within the outer membrane and are generally not exposed to the surface. Between 7 and 11 flagella are inserted subterminally and bipolarly to the protoplasmic cylinder of *B. burgdorferi* sensu lato. Numbers of flagella vary among other *Borreliae*. The flagella run parallel to the long axis and overlap in the middle of the spirochete. Flagellin, with a molecular weight of 41 kDa, is the predominant flagellar protein. An antibody response to flagellin is a consistent feature in all stages of Lyme disease. Despite the presence of high concentrations of flagellar antibodies, Lyme disease continues to progress, suggesting that flagellin does not induce a protective immune response.

The structure and importance of the protoplasmic cylinder remains undefined. The cell wall contains muramic acid and ornithine as part of the peptidoglycan. Another component may be lipopolysaccharide. The Jarisch–Herxheimer reaction (characterized by a transient high fever), which can occur in Lyme disease patients after treatment with antibiotics, may be due to the sudden release of lipopolysaccharide from lysed organisms. Many patients have experienced a Jarisch–Herxheimer reaction following antimicrobial therapy.

Borreliae can be cultivated in artificial medium; however, the bacteria multiply slowly. Generation times range from 8 to 15 h (*B. burgdorferi*) to 26 h (*B. recurrentis*). Continuous passage of *Borreliae* in artificial medium alters the antigenic structure and renders the bacteria noninfectious.

The clinical presentation alone is usually sufficient to diagnose relapsing fever. In contrast, diagnosis of Lyme disease is often difficult because of the variety of symptoms that can develop. Visualization of *B. burgdorferi* sensu lato in blood has not been successful because Lyme disease spirochetes rapidly disseminate into tissues. Silver staining has been used to demonstrate spirochetal forms in both biopsy and autopsy tissues; however, spirochetes cannot be positively identified.

Lyme disease spirochetes have been successfully cultured *in vitro* from blood, cerebrospinal fluid and synovial fluid but only a small number of these cultures have yielded organisms. In contrast, recovery of *B. burgdorferi* sensu lato from EM skin lesions has been more successful. Polymerase chain reaction (PCR) technology has also been used to directly detect Lyme disease spirochetes in patients. To date, PCR testing appears to be useful for recovery of *B. burgdorferi* sensu lato DNA from atypical EM

lesions, cerebrospinal fluid and synovial fluid, provided the laboratory has sufficient expertise with the technology.

In many cases, serologic evidence of infection with Lyme disease spirochetes is the only option available to clinicians. Unfortunately, gross inaccuracies caused by the lack of specificity of conventional diagnostic assays and their subjectivity have made misdiagnosis and overdiagnosis common. These factors have contributed to confuse the general public and make many clinicians distrust serologic testing. During the past several years, however, diagnostic assays have been greatly improved. Unfortunately, there is currently no single assay that offers sufficient sensitivity and specificity to become the 'gold standard' of Lyme disease testing, although detection of borreliaecidal antibodies in Lyme disease patients offers promise. A flow cytometric borreliaecidal antibody test that measures the killing of live spirochetes after they were inoculated in the patient's serum and complement showed a sensitivity of 72% and more than 98% specificity. Regardless, quality laboratory procedures are available, provided results are obtained from experienced laboratories and interpreted correctly and the clinician understands the advantages and disadvantages of each laboratory procedure.

In early studies of the pathogenesis of Lyme disease, a major obstacle was the lack of suitable animal models. Rabbits and guinea pigs infected with *B. burgdorferi* develop skin lesions which histologically resemble human EM. These lesions, however, are not consistently induced and are the only clinical manifestations detected. Disseminated infection occurs in mature hamsters, rats and mice but clinical manifestations similar to those seen in human Lyme disease do not occur, despite persistence of spirochetes in the tissues. The hallmark of chronic *B. burgdorferi* sensu lato infection in humans, Lyme arthritis, appears to be observable in rodent models only when the immune system is immature or compromised. Rhesus monkeys have been shown to develop clinical signs and symptoms similar to localized and disseminated human infection; however, development of clinical arthritis only occurred in a small percentage of infected animals. In addition, the high costs associated with these animals has precluded widespread use of this Lyme disease model.

Despite these imperfections, animals models have been used extensively to elucidate pathogenic mechanisms of *B. burgdorferi* sensu lato. Lyme disease spirochetes have been shown to stimulate various inflammatory cytokines, including interleukin 1 (IL-1), IL-6 and tumor necrosis factor α (TNF α), and

several autoimmune mechanisms which appear to play a role in pathogenesis.

Animal models also continue to play a vital role in efforts to develop an effective Lyme disease vaccine. The role of cell-mediated immunity remains largely unknown; however, an important role for antibody-mediated immunity after vaccination has been established. The induction of antibodies, termed borreliacidal, that can specifically kill *B. burgdorferi* sensu lato are often responsible for antibody-mediated protection. Vaccination of animals with several individual Osps, including Osp A, Osp B, Osp C, and a 39 kDa protein have provided protection against Lyme disease spirochetes. Concomitantly, borreliacidal antibodies against Osp A, Osp B and the 39 kDa protein have been detected *in vitro*.

Osp A has emerged as the leading Lyme disease vaccine candidate and the efficacy of several recombinant Osp A vaccines is being investigated in animals and humans. Clinical trials have demonstrated safety in human volunteers; however, several significant obstacles must be overcome before induction of long-term comprehensive protection can be demonstrated. Most importantly, the success of Osp A vaccination appears to be dependent on the induction and long-term maintenance of high concentrations of borreliacidal antibodies. The present formulations of the Osp A vaccine have not maintained and sustained high concentrations of borreliacidal antibodies.

An anamnestic response will likely occur too slowly to prevent infection. Shortly after infection with *B. burgdorferi* sensu lato, the spirochetes become refractory to killing by borreliacidal antibodies. High levels of borreliacidal antibodies are detectable in sera from humans with all stages of Lyme disease; however, spirochetes are not eliminated. A recently developed flow cytometric test for detecting these highly specific borreliacidal antibodies is useful for confirming a Lyme disease diagnosis, and widespread availability of this test should greatly improve Lyme disease testing. However, induction of protective levels of anti-Osp A borreliacidal antibodies for extended periods of time has been difficult, even after vaccination of animals with

high concentrations of Osp A in combination with adjuvants.

In addition, experimental Osp A vaccines comprise a single protein, despite the fact that Osp A is antigenically polymorphic. Thus, vaccination provides little or no protection against heterologous *B. burgdorferi* sensu lato isolates. Significant frequencies of anti-Osp A escape mutants have also been observed in animals after vaccination with a single Osp A protein. More recently, researchers demonstrated down-regulation of Osp A expression and upregulation of other Osps shortly after infection of the vertebrate host. Thus, the incorporation of multiple Osp A proteins and other *B. burgdorferi* sensu lato Osps, especially Osp C, appears necessary for comprehensive protection against the Lyme disease spirochete.

BRUCELLA, INFECTION AND IMMUNITY

Brucellae are gram-negative coccobacilli, which lack capsules or flagellae. They establish persistent intracellular infections in mammals (Table 1). In animals, brucellosis typically affects the reproductive organs, and abortion is usually the only outward sign of the disorder. Human brucellosis is either an acute febrile disease or a chronic disease with a wide variety of symptoms, often difficult to diagnose. It is not associated with abortion. It is a true zoonosis, in that virtually all human infections are acquired from animals (Figure 1). Typically, brucellae may infect handlers of infected livestock or carcasses, and people consuming unpasteurized milk products. Aerosol transmission is a hazard in abattoirs. Diagnosis of brucellosis often rests on serology, but the protective immune response is cell mediated.

Characteristics of the organisms and their antigens

Species of *Brucella* were originally classified according to the reservoir hosts (Table 1). The species are differentiated in the laboratory by colony morphology, growth requirements, various biochemical tests and lysis by bacteriophages. Nevertheless, DNA hybridization studies suggest they are so closely related that they should be classified as a single species.

Fresh isolates of most *Brucella* spp. are smooth,

but dissociation occurs readily into rough or mucoid colonies. *B. ovis* and *B. canis* are normally rough or mucoid and lack the O chains of lipopolysaccharide (LPS). *Brucella* LPS is less toxic, less pyrogenic and less effective as a polyclonal activator than that of most gram negatives. Nevertheless, it appears to be the main virulence factor of *Brucella* species.

Two different O chains occur on *Brucella* LPS: A, generally associated with *B. abortus*, and M, with *B. melitensis*. However, some *B. abortus* biovars carry M antigens, and some common *B. melitensis* carry A antigen. Both are linear polymers of an unusual amino sugar, perosamine (4,6-dideoxy-4-formamido-D-mannopyranose). They differ in that the A chain sugar molecules are always linked 2–1, whereas the M chain has a 3–1 linkage at every fifth junction. They can be distinguished by monoclonal antibodies, or by polyclonal serum rendered specific by cross-absorption. Cross-absorption is needed because the core structure of LPS is common to all species.

Other cell envelope antigens include the outer membrane proteins (MPS) which fall into two molecular weight ranges, 25–27 kDa and 36–38 kDa. The latter act as porins. In addition there are more than 30 internal antigens identified by western blotting or immunoelectrophoresis.

Table 1 Host ranges of the genus *Brucella*

Species	Colony type ^a	Predominant hosts	Occasional hosts ^b
<i>B. melitensis</i> (3 biovars)	S	Sheep, goats	Cattle, humans
<i>B. abortus</i> (7 biovars)	S	Cattle	Sheep, goats, horses, other domestic and wild ungulates, dogs, humans
<i>B. suis</i> (5 biovars)	S	Biovar 1: pigs Biovar 2: hares Biovar 3: pigs Biovar 4: reindeer Biovar 5: wild rodents	Humans Pigs Humans Humans
<i>B. neotomac</i>	S	Desert wood rat ^c	Not reported
<i>B. ovis</i>	R	Rams	Ewes
<i>B. canis</i>	R	Dogs	Humans

^a Wild-type on isolation. S, smooth; R, rough. Avirulent R mutants of S strains are readily obtained on laboratory media.

^b Not a complete list – examples only.

^c *Neotoma lepida*.

Figure 1 Brucellosis is a true zoonosis with different bacterial species infecting different animal species, and only incidentally infecting humans, often as a result of occupational hazard or drinking unpasteurised milk.

Immune responses of the host

Protective immunity

The primary antibody response to *Brucella* infection in humans involves early immunoglobulin M (IgM) production followed by a switch to IgG and IgA. IgE can also be detected by radioimmunoassay. IgM persists for an unusually long period into the late stages of the disease and in subclinical infection. It is interesting to speculate that this might relate to the T cell-independent nature of the major antigen, LPS, acting on B cells without causing class switching. Notwithstanding the importance of antibody in serodiagnosis of brucellosis, the role of antibody in protection is probably confined to pre-existing mucosal antibody reducing the likelihood of initial infection.

As facultative intracellular bacteria, brucellae are controlled by the activation of macrophages and the formation of granulomas to localize the infection. In

experimental infection of mice, it has been shown that both CD4⁺ and CD8⁺ T lymphocytes are involved. The function of the CD8⁺ T cells is apparently to lyse ineffective macrophages and non-professional phagocytes to release the bacteria for phagocytosis by activated macrophages. The function of CD4⁺ T cells is to produce interferon γ (IFN γ) and other cytokines to activate and attract macrophages.

Depletion of IFN γ from infected mice by injection of monoclonal antibody specific for IFN γ increases bacterial numbers and suppresses the attraction of macrophages to the infected tissues. Even more dramatic are the effects of depleting interleukin 12 (IL-12), the cytokine which controls the differentiation of T cells and natural killer (NK) cells to produce IFN γ . Injection of antibody to IL-12 prevents IFN γ production by the T cells, prevents the influx of cells which causes splenomegaly, and grossly exacerbates

bacterial numbers over a prolonged period of time. Other cytokines produced during experimental infection include IL-1, tumor necrosis factor α (TNF α), IL-6, macrophage colony-stimulating factor (M-CSF), granulocyte colony-stimulating factor (G-CSF). TNF α is important early in infection, either directly activating macrophages or stimulating the NK cells to produce IFN γ . Its depletion also increases early bacterial numbers and suppresses splenomegaly but, in contrast to the effect of IL-12 depletion, the mice develop IFN γ -producing T cells and recover.

In humans, the tissue lesions produced by *Brucella* sp. consist of minute granulomata, comprising epithelioid cells, neutrophils, mononuclear leukocytes and some giant cells. Necrosis is not common, and abscesses do not form, except in *B. suis* infection. Hepatosplenomegaly is a common clinical manifestation, a symptom shared by experimental mice. As with experimentally and naturally infected animals, human patients develop delayed-type hypersensitivity (DTH), a correlate of the cell-mediated resistance to infection, but also a cause for immunopathology.

Immunopathology

Immunopathology is a major factor in the disease. The granulomata which form at the foci of infection provide the main histopathologic signs. A pathogenic role for immune complexes has been suggested but there is no correlation between their levels and severity of disease. In people who have been sensitized by previous infection, albeit subclinical, needlestick injury can be followed within 24–48 h by a severe, generalized DTH response which resembles many aspects of the infection itself. The ability of components of brucellae to induce polyclonal activation of B lymphocytes could explain the high incidence of autoantibodies in acute infection. Alternatively, the presence of stress proteins which have been conserved across species and cross-react with mammalian proteins have been implicated in autoimmune sequelae of other infections, and may be important in brucellosis also.

Serology

Because of the nonspecific nature of the symptoms of human brucellosis, and the difficulty of isolating the causative organisms, diagnosis often must be made serologically. Most of the antibody detected is directed towards the LPS, with some specific for protein antigens. A variety of tests have been used, including agglutination, complement fixation, precipitation, radioimmunoassay, indirect fluorescence antibody assays and ELISA. To date, the agglutination assay remains the most widely used,

although this is likely to be replaced by ELISA when better standardization is achieved. A feature of the agglutination assay has been the prozone, seen in high-titer sera, and blocking antibodies. The majority of studies suggest that these are IgA, although some have found blocking antibody amongst IgG. The problems of prozone or blocking antibody can be overcome by further dilution of the serum or the use of an indirect agglutination assay. Where it is necessary to distinguish IgM and IgG antibodies, 2-mercaptoethanol is used to inactivate IgM agglutination, leaving 2-mercaptoethanol-resistant IgG.

In domestic animals intradermal testing for DTH is the most convenient way of establishing the presence of infection in the herd. Nevertheless serology is the best way of detecting infected individual animals.

Evasive strategies by the organism

These bacteria can survive within the phagocytic cells of the host. Extracts of *B. abortus* have been reported to inhibit phagosome–lysosome fusion in macrophages, degranulation of neutrophils and the oxygen-dependent antibacterial system of bovine neutrophils. The organisms may spread from the initial site of infection either within these cells or free in the bloodstream. They localize in certain target organs, such as lymph nodes, spleen, liver, bone marrow and, especially in animals, reproductive organs. The presence of mesoerythritol in the testes and placenta of ruminants and pigs stimulates enormous multiplication of brucellae in those tissues, leading to infertility and abortion. However, erythritol is absent in humans.

Vaccines

While LPS is the target of antibodies, there is a spectrum of proteins which can stimulate T cells. A number have been identified. Some were found to be stress proteins. Nevertheless, a defined vaccine is some time away, since, as with other intracellular bacteria, live attenuated vaccines are the only ones so far shown to be effective in the induction of cell-mediated resistance.

B. abortus strain 19 is used to immunize cattle, while *B. melitensis* strain Rev 1 is used in sheep and goats. However, vaccination of humans has not been widely used outside Russia due to the questionable safety of these strains. Accidental infection with vaccines is a hazard for veterinarians exposed to needlestick injuries or splashes on to the conjunctiva.

The preferred approach to prevention of human infection is the pasteurization of milk products and

the ultimate eradication of infected herds. Once infection in domestic animals is reduced by vaccination, vaccination is replaced by testing followed by slaughter of infected animals. At this stage, vaccination of the herds only leads to confusion, since neither the serological tests used nor DTH screening can distinguish between infected and vaccinated animals. Although vaccination of very young animals usually results in antibody dropping to undetectable levels by the time surveillance of the herd is undertaken, remaining positives lead to confusion as to whether or not they are infected.

BRUTON'S AGAMMAGLOBULINEMIA

Mary Ellen Conley, Department of Pediatrics, University of Tennessee, and St Jude Children's Research Hospital, Memphis, Tennessee, USA

Historical background

In 1952 Colonel Ogden C Bruton reported the case of an 8-year-old boy with a 4 year history of recurrent bacterial sepsis, osteomyelitis and otitis. This child failed to make antibodies to pneumococcus after repeated antigenic challenge. In a seminal observation, Bruton noted that the patient's serum lacked the gamma globulin fraction by electrophoretic analysis but was otherwise normal. This was the first case in which an abnormal result in a laboratory study explained the clinical problems and dictated the therapy for an immunodeficient patient. The patient was treated with gamma globulin and had a marked decrease in the incidence of infection. In the next 5 years many similar patients were reported.

Most of these patients could be divided into one of two groups. The first group consisted of adults who had the onset of recurrent or persistent infections after early childhood. Males and females appeared to be equally affected and the disorder could not be accounted for by a single gene defect by mendelian inheritance. This disorder came to be called acquired hypogammaglobulinemia or common variable immunodeficiency. The patients in the second group were boys who had the onset of their disease in the first 2 years of life. Many of these children had similarly affected brothers, maternal uncles or cousins. This disorder is now referred to as X-linked agammaglobulinemia (XLA), congenital agammaglobulinemia or Bruton's agammaglobulinemia.

Studies performed in the 1970s showed that patients with XLA had markedly reduced numbers

of B cells in the peripheral circulation; however, pre-B cells could be found in their bone marrow, suggesting that stem cells could enter the B cell lineage but they could not progress through normal B cell differentiation. In 1986, preliminary linkage studies mapped the XLA defect to the midportion of the long arm of the X chromosome. The same year, X chromosome inactivation studies performed on the B cells of carriers of XLA, the mothers of affected boys, showed that the XLA gene product was expressed in B cells and it was not transportable between cells. In 1993, two groups, using positional cloning or analysis of a candidate gene, independently showed that XLA was due to mutations in the gene encoding a cytoplasmic tyrosine kinase which is now called Btk (Bruton tyrosine kinase) (Table 1).

Clinical characteristics

Most patients with XLA are healthy at birth and remain well for the first few months of life. Recurrent infections, particularly otitis and pneumonia, usually develop sometime during the second 6 months of life, after the loss of maternally acquired antibody. The majority of patients with XLA are evaluated for immunodeficiency before 3 years of age. However, 20–30% of patients present later; some of these patients have higher concentrations of serum immunoglobulins and/or more B cells than are typical for XLA. A helpful clinical clue to the diagnosis of XLA is unusually small peripheral lymph nodes and tonsils. Germinal follicles, which constitute a considerable proportion of the volume of lymph nodes, are largely made up of B cells. In the absence of B cells, lymph nodes are quite small. Except for signs of past infection, there are no other striking physical findings. By the time of diagnosis approximately 80% of patients have experienced recurrent upper and/or lower respiratory tract infections. Diarrhea and pyoderma are also frequently seen before diagnosis and initiation of therapy. Between

20 and 30% of patients have experienced sepsis, meningitis, arthritis or failure to thrive. Profound neutropenia is present at the time of diagnosis in about 25% of patients. Overwhelming bacterial sepsis with rapid demise is not unusual. The most frequent infecting organisms in patients with XLA, and in all other patients with hypogammaglobulinemia, are *Haemophilus influenzae*, *Streptococcus pneumoniae* and *Staphylococcus aureus*.

After diagnosis and initiation of gamma globulin replacement therapy, upper and lower respiratory tract infections may continue to be a problem, particularly if the patient has developed chronic pulmonary changes prior to diagnosis. Diarrhea due to Giardia is not uncommon in patients with XLA but is usually easily treated. Mycoplasma or ureoplasma infections can cause persistent arthritis, pneumonitis or urologic problems. Between 5 and 10% of patients with XLA have chronic enteroviral infections resulting in meningitis/encephalitis, arthritis or a dermatomyositis-like syndrome. These infections are often slowly progressive and fatal. Although echovirus is the most common organism, vaccine-associated polio and Coxsackie have also been isolated.

High-dose gamma globulin therapy is expected to decrease the incidence of chronic lung disease and enteroviral or mycoplasma infections in patients with XLA; however, it has been the source of hepatitis C infection in some patients. At the present time, the majority of adolescents with XLA have intermittent or chronic mild sinusitis or bronchitis but are otherwise completely well with normal growth and development.

Laboratory characteristics

The hallmarks of XLA are markedly decreased concentrations of serum immunoglobulins and an almost complete absence of B cells in the peripheral circulation. The serum immunoglobulin G (IgG) is usually less than 2 mg ml⁻¹, and the IgM and IgA are less than 0.1 mg ml⁻¹. B cells, which constitute 5–18% of the peripheral blood lymphocytes in the normal individual, cannot be detected using standard techniques; however, a small number (0.005–0.1% of peripheral blood lymphocytes) are uniformly present. As evaluated with antibodies to surface markers, these B cells have an immature phenotype that is similar to that seen in B cells from X-linked immunodeficient (xid) mice. Epstein-Barr virus (EBV)-transformed B cell lines, produced from the blood of patients with XLA, make normal immunoglobulins with correct rearrangements of V, D and J gene segments. A disproportionate number of the

Table 1 Characteristics of Bruton's agammaglobulinemia

X-linked recessive (occurs only in males)
Onset in the first 3 years of life
Recurrent infections with encapsulated bacteria
Sinusitis, otitis, bronchitis and pneumonia
Increased susceptibility to mycoplasma, enterovirus and hepatitis C
Marked decrease in serum IgG, IgM and IgA
Profoundly reduced numbers of B cells
Pre-B cells present in the bone marrow
Treatment with gamma globulin and antibiotics
Mutations in the gene for Bruton's tyrosine kinase (Btk)

pre-B cells found in the bone marrow of patients with XLA are at the earliest stage of development and a reduced percentage of them are in the S phase of the cell cycle.

Abnormalities in cell lineages other than B cells have been reported; however, these abnormalities may be secondary to the marked reduction in B cell numbers or the hypogammaglobulinemia rather than a direct effect of the genetic defect.

Bruton tyrosine kinase

Bruton tyrosine kinase (Btk) is a 659 amino acid member of a recently identified subfamily of src-related cytoplasmic tyrosine kinases (Figure 1). It is expressed throughout B cell and myeloid development but it is not expressed in nonhematopoietic cells. Like src, Btk has a carboxy-terminal catalytic domain adjacent to SH2 and SH3 (src homology 2 and 3) domains. However, unlike src but similar to the other members of its subfamily, which include Tec, Itk and Bmx, Btk has an amino-terminal PH (pleckstrin homology) domain followed by a proline-rich region. Although the substrates phosphorylated by Btk have not yet been identified, like other tyrosine kinases, Btk is thought to function in signal transduction. This view is supported by the observation that the protein-protein interaction domains of Btk bind to other molecules known to be involved in signal transduction, including src family members, the $\beta\gamma$ subunit of G proteins, protein kinase C and cbl.

Btk is phosphorylated and its kinase activity is increased by stimulation of a variety of cell surface receptors, including, and perhaps most importantly, the B cell receptor complex (BCR). After cross-linking of cell surface IgM, src family members phosphorylate Btk, which then increases its catalytic activity by autophosphorylation. This process is associated with movement of Btk to the inner surface of the cell membrane.

The well-characterized murine immunodeficiency,

xid, is caused by an amino acid substitution in the PH domain of Btk. The phenotype of the xid defect appears to be milder than the XLA defect. Mice with either the spontaneous Btk mutation or a null mutation in Btk induced by homologous recombination have reduced concentrations of serum IgM and IgG3 and they lack a mature population of B cells; however, they do have an antibody response to T cell-dependent antigens and they have relatively normal concentrations of serum IgG1, IgG2a and IgG2b. The phenotype of the xid mice suggests that Btk is required not only at the transition from pre-B cell to B cell but also at later stages of differentiation.

Genetics

Bruton's agammaglobulinemia occurs in all racial groups, with a prevalence of between 2 and 8 per 1 000 000. As is true with all X-linked disorders that are lethal without medical intervention, the disorder is maintained in the population by the occurrence of new mutations. This has two important consequences. First, approximately half of the patients with the clinical and laboratory characteristics of XLA have no family history of the disorder because they are the first manifestation in their family of a new mutation. Second, the mutations in Btk that cause XLA are independently derived and highly variable.

The gene for Btk consists of 19 exons spread over 37 kb at Xq22. Human Btk has over 95% homology to murine Btk and 58% homology to a drosophila kinase, Dsrc28C. Over 100 different mutations in Btk have been identified. Although deletions that are detectable by Southern blot analysis do occur, they constitute less than 10% of the mutations in this gene. About one-third of the mutations result in amino acid substitutions, the majority of which are in the kinase domain; however, amino acid substitutions in the PH domain and the SH2 domain have also been seen. The remaining mutations are almost equally divided between single base pair substi-

Figure 1 Structure of the 659 amino acid cytoplasmic tyrosine kinase, Btk. The amino-terminal pleckstrin homology domain (PH) is followed by a proline rich region (Pro), and SH2 and SH3 domains and the catalytic domain. The mutations causing amino acid substitutions in patients with XLA and the codons affected by those mutations are shown. Some codons have been altered by two different mutations; xid mice have an amino acid substitution in codon 28 in the PH domain.

tutions that cause premature stop codons, small insertions or deletions that result in frameshift mutations and splice defects. These mutations are spread almost evenly throughout the Btk gene. Studies done on EBV-transformed cell lines or myeloid cells from patients with XLA indicate that this last group of mutations (stop codons, frameshifts and splice defects) usually result in poor accumulation of the Btk mRNA in the cytoplasm. Thus, these mutations are functionally equivalent.

Attempts to correlate the severity of the clinical manifestations of XLA with specific mutations in Btk suggest that the site or type of mutation may influence the phenotype. Amino acid substitutions in the SH2 domain or noncritical regions of the catalytic domain are sometimes seen in patients with milder disease. However, additional factors, including other genes, past infections and therapy, may also influence the phenotype of patients with XLA.

Differential diagnosis

X-linked agammaglobulinemia should be distinguished from two other X-linked disorders that result in hypogammaglobulinemia in infant males. X-linked severe combined immunodeficiency (SCID), which is due to mutations in the common γ chain of cytokine receptors, is associated with the onset of persistent fungal and viral, as well as bacterial, infections in the first 6 months of life. Laboratory studies show normal or increased proportions of B cells but markedly decreased numbers of T cells, and absent proliferation in response to T cell mitogens. Mutations in the gene for CD40 ligand cause X-linked hyper-IgM syndrome, a disorder in which serum concentrations of IgG and IgA are markedly decreased but the level of IgM, while not always strikingly elevated in infancy, is higher than that usually seen in XLA. Patients with X-linked hyper-IgM syndrome have normal numbers of peripheral blood B cells and T cells. Patients with common variable immunodeficiency can be distinguished from patients with XLA in that they usually have somewhat higher concentrations of serum immunoglobulins and normal or near normal numbers of B cells in the peripheral circulation. T cell number and function may be abnormal in patients with common variable immunodeficiency. A small number of girls in whom both the clinical and laboratory findings are indistinguishable from XLA have been reported, suggesting that there is one or more autosomal recessive disorder(s) phenotypically identical to XLA.

Therapy

Patients with XLA are treated with gamma globulin replacement therapy and liberal use of antibiotics. All live viral vaccines should be avoided. Although the identification of Btk as the defective gene in XLA sets the stage for gene therapy, a better understanding of the regulation and function of Btk, as well as improved technology of gene transfer, will be required before this goal can be achieved.

BUNYAVIRIDAE, INFECTION AND IMMUNITY

James S Porterfield, formerly of the Sir William Dunn School of Pathology, University of Oxford, Oxford, UK

In 1943 a virus was isolated from a pool of wild-caught *Aedes* mosquitoes collected in an uninhabited area of Semliki Forest in western Uganda known as Bunyamwera. The virus was unrelated to yellow fever virus, or to any of the 20 or so arthropod-borne viruses or 'arboviruses' then known, and it was named Bunyamwera virus. Although antibodies against Bunyamwera virus were detected in some residents of nearby villages, no disease association was apparent, and the virus appeared to be little more than a virological curiosity. By 1960 about a dozen arboviruses isolated in North and South America, Europe, Africa and Asia had been shown to be serologically related to Bunyamwera virus, and this number increased over the next decades. More than 50 years after its isolation, Bunyamwera virus remains an unimportant virus in terms of human disease, causing at the most a mild fever with a rash, but it has been intensively studied as the type species both of the genus *Bunyavirus* and of the large and diverse family Bunyaviridae which now contains more than 300 members placed in five different genera, *Bunyavirus*, *Hantavirus*, *Nairovirus*, *Phlebovirus* and *Tospovirus* (Table 1).

Although the majority of Bunyaviridae resemble the type species in being of minor medical importance, the family does contain a number of major pathogens of humans and/or animals. Most bunyaviruses are transmitted by mosquitoes or by *Culicoides*, most phleboviruses by *Phlebotomines*, and all nairoviruses by ticks, whereas hantaviruses are not arthropod-borne, but are zoonotic agents capable of infecting humans after close contact with infected animals, mainly rodents and voles. Tospoviruses are thrip-transmitted plant viruses such as tomato spotted wilt and related viruses. They are of no medical or veterinary interest, but are included in the Bunyaviridae on the basis of their close physical, biochemi-

cal and genetic similarities to viruses in the other genera. They illustrate the great genetic diversity shown by members of this substantial family.

Characteristics of the Bunyaviridae

Bunyaviridae are enveloped RNA viruses about 100 nm in diameter containing a tripartite, single-stranded RNA genome of negative polarity (Figure 1). Virions contain three main proteins, namely the envelope glycoproteins G1 and G2, and the nucleocapsid protein N, together with a minor large protein L. The three viral RNA species are designated as small (S), medium (M) and large (L), of which the S RNA encodes the N protein, the M RNA encodes the two envelope glycoproteins G1 and G2 and the L RNA encodes the large, virion-associated polymerase protein L. Three different expression strategies are used to generate the nonstructural proteins of the S

Figure 1 Schematic representation of a bunyavirus particle, showing the two virion spike glycoproteins, G1 and G2, and the three RNA genome segments L, M and S encapsidated by the N (nucleocapsid) protein and associated with the L (RNA-dependent RNA polymerase) protein. From J.F. Simons, PhD Thesis, Stockholm, 1992.

<i>Phlebovirus</i> (57)	Sandfly	Phlebotomus (44)	Alenquer, Candiru, Chagres, <i>Sandfly fever, Naples & Sicilian</i> , Punta Toro, <i>Rift Valley Fever</i> ^b , Toscana
	Tick	Uukuniemi (13)	Uukuniemi, Zalev-Terpeniya
<i>Unassigned</i> (53)	Mosquito		Bangui, Kasokero, Tataguine
	Tick		Bhanja, Keterah, Tamdy, Wanowrie
<i>Tospovirus</i> (>3)	Thrip	Tomato spotted wilt	

The approximate number of viruses in the genus or serogroup is given in parentheses.

^aViruses causing important animal diseases.

^bMosquito vector for Rift Valley fever virus.

Viruses in italics are responsible for important human diseases.

segment, and two different strategies are found for the M segment. Viral replication occurs in the cytoplasm of infected cells, using a Golgi-associated morphogenesis with budding into intracytoplasmic vacuoles.

The most important bunyavirus disease of man is probably California encephalitis, which occurs in North America and affects mainly children. Most infections are due to La Crosse, snowshoe hare or Keystone viruses rather than to California encephalitis virus itself. These viruses are maintained in nature in small rodents and are transmitted to man by mosquito bites, *Aedes triseriatus* being the principal vector. Aino and Akabane are two Simbu serogroup

bunyaviruses which are causes of congenital malformations (arthrogryposis, hydranecephaly and anencephaly) in sheep, goats and cattle in Japan, Australia, East and South Africa, Cyprus and Israel. Oropouche virus is another Simbu serogroup bunyavirus which has caused thousands of human infections in Brazil, many involving the central nervous system, although fatalities are very rare.

Hantaan virus and related hantaviruses cause Korean hemorrhagic fever, otherwise known as hemorrhagic fever with renal syndrome (HFRS), a severe and often fatal infection that occurs across Asia from China into Europe. In Scandinavia, Puumala and related viruses cause a much milder clinical

syndrome known as nephropathia epidemica. In 1993 a new and severe illness known as Hantavirus pulmonary syndrome (HPS) was recognized in the southwestern USA, and by 1996 similar infections had been identified in Canada, Brazil, Paraguay and Argentina, associated with three different hantaviruses, Sin Nombre, Black Creek Canal and Bayou viruses. The overall mortality in 128 confirmed cases of HPS in the USA to February 1996 was 50%, with a peak incidence in June and July. Most cases have been in rural residents. Rodent association with human disease is indicated in Table 2.

Crimean–Congo hemorrhagic fever, which occurs in countries of the former USSR, the Middle East and Africa, as far south as the Cape, is the most important *Nairovirus* infection, having a mortality of around 20%. Deaths have occurred in hospital staff following surgical intervention in patients who have presented with severe intestinal bleeding.

Phlebotomus fever occurs in the Mediterranean and Middle East regions as a mild, but troublesome erythematous fever, but the most important *Phle-*

bovirus is Rift Valley fever virus, transmitted by mosquitoes rather than phlebotomines. Rift Valley fever is enzootic in sub-Saharan Africa and produced a major human epidemic with some 600 deaths in Egypt in 1977; a decade later another epidemic occurred in Mauritania, and there have been many smaller outbreaks in humans and animals.

Immune responses of the host

Bunyaviridae are highly immunogenic, inducing neutralizing antibodies which are type specific but show limited cross-reactivity within the genus. Recovery is normally followed by solid protection against reinfection. In some infections the immune response occurs too late to prevent invasion of the central nervous system or the liver. Thus animal infection with Rift Valley fever virus can produce overwhelming infection, with liver necrosis and high mortality. Some American hantaviruses target the lungs, rather than the liver, kidneys or central nervous system, resulting in hantavirus pulmonary syndrome. The intense inflammatory response in these infections leads to the release of mediators followed by increased vascular permeability throughout the lungs, and consequent clinical disease.

Antibodies against the G1 glycoprotein neutralize viral infectivity, and inhibit hemagglutination. The nucleocapsid protein is the dominant antigen in complement fixation tests. There have been few studies of cell-mediated immunity, but mice infected with Tahyna *Bunyavirus*, which normally recover following a subclinical infection, die when immunosuppressed with cyclophosphamide. Circulating immune complexes have been reported in nephropathia epidemica.

Evasive strategies by the organism

The possession of a segmented genome allows the possibility of genetic reassortment, which has been demonstrated in the laboratory and also occurs in nature.

Vaccines

Formalin-inactivated veterinary vaccines against Rift Valley fever and Nairobi sheep disease have been available for a number of years, but vaccines for use in humans are still experimental. Laboratory workers immunized with inactivated Rift Valley fever virus vaccines develop high levels of neutralizing antibodies and remain free from infection. Attenuated strains of Rift Valley fever virus have been developed with a view to their possible use as live viral vaccines. Hantavirus vaccines are being developed: one prepared using brains of newborn

BURSA OF FABRICIUS

Paavo Toivanen, Department of Medical Microbiology, Turku University, Turku, Finland

The bursa of Fabricius is a sac-like lymphatic organ present only in birds and situated dorsal to the cloaca. It was first described by Hieronymus Fabricius, Professor of Anatomy and Surgery at Padua University in 1565–1610. Fabricius erroneously proposed the bursa to be a female organ into which the cockbird delivers semen, so that it may be stored. It was William Harvey, the most famous of the many students of Fabricius, who pointed out that the organ was present in both sexes and could not serve the function assumed by Fabricius. Thereafter it took more than three centuries until a serendipitous experiment by Bruce Glick in 1955 revealed the central role of the bursa of Fabricius in antibody production. Glick was involved in a demonstration for students, of antibody production against *Salmonella*. The only animals available were from an experiment where the birds had had the bursa of Fabricius removed soon after hatching. These birds failed to produce the antibody.

Development and structure

The bursal anlage is first observed in the chicken embryo at 4 days of incubation as an epithelial bud in the cloacal region. While enlarging, the bud becomes increasingly vacuolized, the coalescence of the vacuoles giving rise to the bursal lumen. Epithelial longitudinal folds are formed on the inner sur-

face of the sac, and the columnal epithelium, covering the plicae, proliferates and forms outgrowths into the underlying lamina propria. Formation of these epithelial buds is dependent on interaction between the mesenchymal and epithelial tissues. Each epithelial bud is colonized by one or two prebursal stem cells. They proliferate vigorously, leading to formation of the medulla of the bursal follicles, which start to appear on day 12 of incubation in the chicken embryo. Prebursal stem cells originate in the intra-embryonic mesenchyme. On arrival at the bursa they have the germ-line immunoglobulin (Ig) genes rearranged, being already committed to development along the B cell lineage. The period of prebursal stem cell arrival in the chicken bursa extends from day 8 to day 14 of incubation. Cells bearing IgM on the surface appear in the bursa on day 12 of embryogenesis. At the time of hatching, about 90% of the bursal cells carry surface IgM and <1% IgG or IgA.

The epithelial anlage of the bursa of Fabricius is decisive in providing differentiation signals to the arriving prebursal stem cells and to their descendants, the bursal stem cells. How the signals are mediated remains unknown, as no definitive evidence, e.g. for existence of a specific bursal hormone, is available.

Epithelial cells within the medulla form a loose cellular network with desmosome connections, and

they are secretory in morphological structure. In addition to epithelial cells, the fully developed bursal medulla contains small lymphocytes, plasma cells and phagocytic histiocytic cells. Less than 1% of the bursal cells are T cells. They are mostly located in a diffusely infiltrated area of lymphoid cells, dorsal to the bursal duct opening to the cloaca. At the time of hatching lymphoid cells also appear in the mesenchymal tissue surrounding each follicular medulla, and a follicular cortex develops. The medulla and cortex are separated by a basement membrane.

At the plical surface against the bursal lumen the epithelial cells differentiate into a follicle-associated

epithelium, with a specific function to phagocytose and transport antigenic material from the bursal lumen into the follicular medulla. The epithelial cells in the follicle-associated epithelium and within the bursal medulla are different in their phagocytic capacity and enzyme activities. Structural organization of the bursa is presented in Figure 1.

At the time of hatching the chick bursa of Fabricius weight 30–40 mg and reaches a maximum of 3–4 g at the age of 2–4 months. Thereafter, with the beginning of sexual maturation, it involutes, and both the lymphoid and epithelial structures have completely disappeared at the age of 6–12 months.

Figure 1 (A) Location of bursa of Fabricius (F) and thymus (T). (B) Cross-section of bursa of Fabricius at the level indicated by a broken line in Figure 1A. The plicae are longitudinal in dorsoventral direction, with a bursal lumen opening ventrally to the cloaca; 4-day-old chick. H & E; magnification $\times 10$. (C) A bursal follicle from the area marked with a square in Figure 1B. The cortex and medulla are separated by a basement membrane (double arrows). The interfollicular epithelium against the bursal lumen is broken by the follicle-associated epithelium (arrow). H & E; magnification $\times 250$. (D) Scanning electron micrograph of plical surface against the bursal lumen. The phagocytosing follicle-associated epithelium appears as clearly distinguishable areas (arrow). Magnification $\times 200$.

Bursectomy

Experiments on birds with the bursal tissue removed have proved crucial in revealing the function of the bursa. Surgical bursectomy in the newly hatched period is not sufficient to prevent migration of B cells into the periphery because the cellular outflow starts during the embryonic period. The same holds true if the surgical bursectomy is carried out during late embryogenesis. More complete results have been obtained when the surgical bursectomy has been combined with *in ovo* treatment with antibodies against the heavy chain of IgM. Surgical removal of the bursal anlage can also be performed before the bursa is populated by prebursal stem cells. However, even in such animals, operated on days 2–5 of incubation, some plasma cells and antibodies with extremely limited antibody repertoire are found, indicating restricted extrabursal B cell maturation.

Other methods of bursectomy include treatment with testosterone or cyclophosphamide. Testosterone given *in ovo* also destroys the epithelial compartment of the bursa, whereas cyclophosphamide leaves it

intact, allowing experimental repopulation by prebursal or bursal stem cells.

Central function

The bursa of Fabricius functions as a central lymphoid organ, required for development of the antigen-specific B cell repertoire. It is necessary for the differentiation of prebursal stem cells into bursal stem cells present in the bursa until the 5th week after hatching. These cells are capable of reconstituting the bursal morphology and specific antibody production when transferred into birds with the bursal lymphoid structures destroyed with cyclophosphamide in the newly hatched period. They comprise a clearly defined stage in the stepwise maturation of the avian antibody-producing cells.

The bursa of Fabricius is necessary for the development of the postbursal B cell population, including the mature antigen-specific B cells and the self-renewing postbursal stem cells. Neither of these populations is capable of homing, in contrast to the

Figure 2 The bursa of Fabricius is necessary for the development of the antigen-specific B cell repertoire. Prebursal stem cells with germ line immunoglobulin genes rearranged are found in the intraembryonic mesenchyme from embryonic (Embr.) day 7 onwards. After arrival in the bursa of Fabricius they become bursal stem cells undergoing extensive, high rate gene conversion, which leads to diversification of the germ line repertoire; these cells need the bursal microenvironment for further maturation. Postbursal cells, present both in the bursa and periphery, include mature antigen-specific B cells and self-renewing postbursal stem cells, capable of further maturation without bursal influence.

prebursal or bursal stem cells, to the cyclophosphamide-treated bursal reticulum, even though they are capable of reconstituting antibody production. In other words, the postbursal cells have passed the stage of bursal development once and for all.

The bursa of Fabricius is necessary for the diversification of the antibody repertoire by providing a site for extensive, high rate gene conversion, which occurs between only one functional V gene (V_{H1} or V_{L1}) and a group of V pseudogenes. The bursal microenvironment selects and promotes for further differentiation bursal stem cells undergoing productive gene conversions, whereas all the others (>90%), probably with unproductive conversion events, die within the bursa. Only minor gene conversion events and somatic point mutations may occur outside the bursa. Molecular events in avian B cell development, as related to the central function of the bursa of Fabricius, are summarized in Figure 2.

Peripheral function

At the time of hatching the bursal lumen opens to the cloaca, allowing environmental antigens to enter the bursal space. The antigens arrive in the cloaca after digestion in the gastrointestinal tract and, with the help of anal sucking movements in the newly hatched period, also through the caudal end of the cloaca. The bursal follicles in turn have contact with the bursal lumen through the phagocytosing follicle-associated epithelium.

A peripheral function of the bursa of Fabricius in the uptake of environmental antigens has an important role in enforcing the expansion of specifically reacting B cell clones which lead to formation of plasma cells and memory cells.

Mammalian equivalent

In the mammalian species the basic, preimmune repertoire of antibody diversity is created in the fetal

liver and bone marrow; the role of intestinal lymphoid tissue is negligible, as it is only weakly developed during the fetal period. In the postnatal expansion and selection of the antibody repertoire the intestinal lymphoid tissue also has an important function in the mammalian species. Peyer's patches play a key role here and have a similar follicular structure as in the bursa of Fabricius. In sheep, Peyer's patches may even have a central function similar to that of the bursa of Fabricius.

Mammalian species generate the antibody repertoire by use of multiple functional V (V_{H1} and V_{L1}) genes when compared to the few functional ones in the avian species. Therefore, by relying on gene rearrangement and other types of somatic diversification, mammals are able to create an extensive antibody repertoire without having an organ particularly specialized for this purpose.

BYSTANDER EFFECTS

Jacques Thèze, Immunogenetique Cellulaire, Institut Pasteur, Paris, France

The fine specificity of effector cells and molecules for an eliciting antigen is usually considered the most important feature of an immune response. However, each immune response can in fact be viewed as being composed of two parts: 1) direct, antigen-specific interactions between cells, resulting in the specific

response towards the antigen; and 2) indirect, non-antigen-specific phenomena, termed 'bystander' effects, resulting in polyclonal responses. Both aspects of the response occur simultaneously and account for the overall response, which comprises both specific and nonspecific events.

Bystander effects, as opposed to antigen-specific interactions, can therefore be defined as the result of cellular interactions occurring without antigen recognition or under conditions where antigen and receptors for antigen are not involved. However, bystander effects are described as phenomena linked to the specific immune response, in that they do not happen on their own but only in connection with a specific response. Cells that are not directly involved in the antigen-specific responses are then 'trans-stimulated' or 'carried along' in the response.

Experimental evidence for bystander effects

The existence of bystander phenomena involving T cell as well as B cell responses has been demonstrated in several *in vitro* experimental models.

T helper cell responses

Specific T cell proliferative responses are elicited by recognition through the T cell antigen receptor of the specific antigenic complex presented by specialized cells. Antigen-specific primed T cells proliferate when challenged *in vitro* with their specific antigen. However, in addition to antigen-specific T cells, the proliferative response can also affect neighboring T lymphocytes with unrelated T cell receptors. Proliferation of bystander T cells occurs independently of antigen recognition on antigen-presenting cells but simultaneously with a specific T cell proliferative response.

B cell responses

One of the most studied bystander phenomena concerns the T cell-dependent B cell response. B cell proliferation and antibody production in response to most soluble proteins requires the participation of T helper cells. This antigen specific T-B cooperation involves linked recognition of the antigen: the epitopes recognized by T and B cells need not be identical but need to be linked. This effect is known as the hapten-carrier effect. The interaction between T and B cells is termed cognate interaction and leads to the secretion by B cells of specific antibodies directed towards the eliciting antigen.

However, several *in vitro* experimental situations suggest that B cell responses can also be elicited under conditions of 'unlinked' recognition, where the antigens recognized by T helper cells and B cells are not covalently linked (bystander help).

When cultured in the presence of naive B cells and antigen, preactivated T cells, or T cell lines specific for a given antigen, elicit a specific B cell response

and antibody production (linked or cognate response). In addition, if another, unrelated antigen is added to the culture, antibody production against this unrelated antigen can also be observed in the culture (unlinked or bystander response). For example, sheep red blood cell (SRBC)-specific T cells induce SRBC-specific antibody production by B cells if SRBC but no horse red blood cells (HRBC) are present in the culture (specific response). However, when SRBC and HRBC are added together, simultaneous production of antibodies to SRBC and to HRBC is observed (specific and bystander response).

Other systems involving the bystander proliferation of B cells in response to specific T cells and antigens have been described. In response to cognate T-B cell interaction syngeneic B cells proliferate but proliferation of allogeneic B cell can also be observed in the culture. In this case, allogeneic B cells do not bear the appropriate major histocompatibility complex (MHC) class II antigens to be recognized by the T cell receptor but they are stimulated by nonspecific signals and/or interactions.

CTL responses

Cytotoxic T cells (CTLs) are differentiated effector T lymphocytes that specifically kill target cells bearing an appropriate antigenic complex (peptide-MHC) recognized by their T cell receptor. However, during this process, nonspecific lysis of unrelated bystander target cells can be observed in the culture. The unrelated target cells do not exhibit the appropriate antigenic complex on their surface and therefore cannot be recognized by the T cell receptor. This phenomenon can be detected *in vitro* using cytotoxic T cell lines of defined specificity and mixing together target cells bearing the appropriate or unrelated antigenic complex.

Possible mechanisms controlling bystander effects

Trans-stimulation of spectator T or B lymphocytes and killing of unrelated target cells imply that a signal can be transmitted to these cells independently of the structures involved in specific antigen recognition. Several explanations have been proposed but the exact mechanism controlling this phenomenon is still a matter of debate. In fact, whether there is an essential difference between specific and bystander effects is not clear and, apart from the process of antigen recognition, mechanisms involved in specific cellular responses could also be responsible for bystander responses.

Cytokines

The most accepted explanation for the existence of such nonspecific effects is the secretion of soluble factors – cytokines – by activated T lymphocytes. During the course of an antigen-specific T cell response, activated T lymphocytes release various lymphokines and, in particular, interleukin 2 (IL-2), IL-4, interferon γ (IFN γ) and tumor necrosis factor β (TNF β ; lymphotoxin). These lymphokines exhibit nonantigen specific, pleiotropic effects. They could act on any other cell present at the site of the immune response. These cells could be T or B lymphocytes, macrophages or target cells for CTLs, provided they are competent to respond to lymphokines (i.e. they express functional surface receptors for these factors). Local effects of such nonspecific factors on neighboring cells not directly involved in the antigen-specific response could explain the involvement of these cells in the overall response: for example, IL-2 could induce the proliferation of T cells and CTLs; IL-4 could transmit activation signals to naive B cells; and IFN γ and TNF β could prepare target cells for CTL lysis.

Stage of lymphocyte activation

Bystander responses could be restricted to particular subpopulations of T or B lymphocytes that would be more susceptible to nonspecific signals. Of particular interest is the question of whether bystander effects involve cells in a particular stage of activation. Since cytokines are likely to be responsible for bystander effects, expression of cytokine receptors by the reacting cell may be an important key in this phenomenon.

Cell surface antigens

Cell-to-cell contact through specific and nonspecific cell surface molecules is obviously an important feature of antigen-specific responses. Similarly, nonantigen-specific cell-to-cell contact could occur during bystander responses. This could involve nonpolymorphic surface molecules, conserved regions of polymorphic cell surface molecules (including MHC molecules), or molecules induced after stimulation.

Polyclonal B lymphocytes can be stimulated in cultures containing T cells and a T cell mitogen or polyclonal activator (such as anti-CD3 or anti-T cell receptor monoclonal antibodies). Under these conditions, polyclonal B cell proliferation and antibody production are observed. Therefore, when efficient

T cell stimulation is obtained, induction of a B cell response without any added antigen can be observed. In this case, bystander B cell stimulation is thought to be dependent upon T–B cell contact and probably involves recognition of B cell surface molecules by T cells (e.g. CD28/B7 interactions).

Similarly for CTL responses nonspecific attachment of any target cell to a specific cytotoxic T lymphocyte by means of lectins causes the lysis of the target cell independently of antigen recognition.

In vivo significance of bystander effects

Although bystander antibody production has been observed for primary responses in the mouse, bystander effects are more readily observed *in vitro* than *in vivo* and their physiological significance has been questioned. Nevertheless, it is known that a polyclonal, nonspecific response frequently accompanies any specific immune response *in vivo*. In particular, B cell responses to a given antigen generally consist of antibodies recognizing the initial antigen, together with a significant production of nonspecific immunoglobulins.

Bystander effects have been evoked to explain the onset of autoimmune responses, as self antigens could be present at the site of the immune response elicited by a foreign antigen. *In vitro* bystander responses can be obtained towards self antigens or normally tolerated antigens.

Finally, bystander phenomena might not have a precise role in the effector phase of the immune response and might simply reflect the existence of a network of connections between the different cellular elements of the immune system. These connections could be maintained by the cytokine network or cell surface molecule interactions. Altogether these interactions may participate in the homeostasis of the immune system.

Characteristics of the organism and its antigens

General features

The caliciviruses (Table 1) comprise a monogenic family of 34 nm, nonenveloped viruses (Figure 1) with characteristic morphology; the surface is covered with cup-shaped depressions (*L. calix*, cup). In some caliciviruses (insect, rabbit) smooth particles are formed, possibly by partial proteolysis. These lack surface projections and are composed of smaller proteins. The calicivirus genome is single-stranded, positive-sense RNA and genes are arranged in two basic patterns.

Table 1 Probable and confirmed caliciviruses

Virus	Serotypes	Infection
San Miguel sea lion virus	16 or more	Vesicular
Vesicular exanthema of swine	13	FMDV-like
Feline calicivirus	1	URTI, stomatitis, limping syndrome
Rabbit hemorrhagic disease virus	1	Hemorrhagic hepatitis
European brown hare syndrome virus	1	Hemorrhagic hepatitis
Human calicivirus	5 or more 'typical' HuCV; 4–9 SRSV	Enteric infections
Hepatitis E virus	1	Hepatitis
Canine calicivirus	At least 2	1 Enteric; 1 vesicular
Infectious stunting calicivirus of chickens	?	Enteric infections
Newbury agent of cattle	2?	Enteric infections
Porcine enteric calicivirus	?	Enteric infections

Figure 1 Particle morphology. Calicivirus particles (34 nm) are built from a single species of capsid protein which gives a characteristic morphology, unique among animal viruses; the structural proteins are linked by arch-like protuberances which ring the points of five- and threefold symmetry, giving the impression of cup-like depressions on the surface of the virus. Partial proteolysis occurring around 72hr pi may degrade the capsid protein forming smooth particles. Figures courtesy of Dr Lorenzo, Istituto Zooprofilattico Sperimentale, Brescia, Italy.

Feline calicivirus, some human caliciviruses, vesicular exanthema and San Miguel sea lion virus possess a genome that contains three sequential open reading frames (ORFs). ORF 1 encodes nonstructural proteins and ORF 2 the capsid protein. ORF 3 is of unknown function but known to be used. This basic structure appears to be flexible and in some viruses ORFs 1 and 2 are fused (e.g. rabbit hemorrhagic disease virus, European brown hare syndrome virus and some human caliciviruses). All viruses appear to synthesize two separate mRNAs, the first to direct the manufacture of ORF 1 proteins, and the second for proteins from both ORFs 2 and 3. Additional open reading frames have been

reported in some of these viruses but there is no evidence that these are functional.

Hepatitis E virus (HEV), also possesses three ORFs but there are significant differences in the sequence of the genes. There is no protein equivalent of ORF 3 in the former viruses; the third ORF of HEV differs in position, sequence and probably in manner of expression. These differences have led to calls for the subdivision of the family. Multiple genera will certainly be required to account for these differences and HEV may be removed to a subfamily or possibly a different family entirely.

Best characterized members

HEV is endemic in parts of eastern Europe, Asia, Africa and South America. Symptoms and transmission are similar to hepatitis A and both infections are more severe in adults. Pregnant women are particularly vulnerable and can develop fulminant hepatitis (20–40% mortality).

Human caliciviruses were recognised as a cause of gastric illness in the 1970s; symptoms include diarrhea, vomiting, pyrexia, anorexia, abdominal pains, aching joints and nausea. Historically, human caliciviruses have been divided according to the clarity of their morphology: those with obvious calicivirus appearance were designated 'typical caliciviruses' (HuCV), e.g. HuCV/Sapporo; those in which the cup structure was indistinct were termed 'small round structured viruses' (SRSV), e.g. Norwalk virus (NV) and Hawaii virus (HV). However, underlying particle architecture and genome organization were similar in both cases and all are now termed human caliciviruses (HuCV); any subdivisions are best made according to RNA sequence. HuCV infect all age groups, although reportedly some occur more often in children (e.g. HuCV/Sapporo) and others in older individuals (NV, HV), but age distribution of infection varies geographically. When infections occur in hosts of the same age the clinical features are indistinguishable. Spread is through contaminated water or food, and especially consumption of shellfish from contaminated waters.

San Miguel sea lion virus (SMSV) is a common cause of death in neonatal pinnipeds and causes abortions in California sea lions. Vesicles or wart-like lesions occur on the tail and flippers.

Vesicular exanthema of swine virus (VESV) was identified in 1932 and is clinically indistinguishable from foot-and-mouth disease in pigs. High fever is often accompanied by severe diarrhea; vesicular lesions form on the tongue, lips and snout and between the toes. Strains vary in severity and some carry a high risk of piglet mortality. VESV is closely related to SMSV and may have originated as a cross-

species infection, transmitted to pigs through uncooked sea lion meat in swill.

Feline calicivirus (FCV) is a major cause of upper respiratory tract infection (URTI) in Felidae but symptoms also include conjunctivitis, stomatitis and sometimes diarrhea. Some strains also cause polyarthritis (limping syndrome). Virulence is variable; mortality may reach 33% in kittens. Recovery is commonly accompanied by virus clearance, but persistent infections can be established in which apparently healthy animals continue to shed virus.

Rabbit hemorrhagic disease virus (RHDV) was described in China (1984), and is now widespread. Adult mortality is 40–90%, but younger animals (<2 months) often survive; this is not due to maternal antibody. RHDV is of major economic and ecologic importance, killing 64 million farmed rabbits in Italy in 1989, and drastically diminishing wild populations. Infection causes high fever and hemorrhagic viremia, and virus reaches high titer in many organs. Retrospective serology shows that a related (presumably nonpathogenic) virus predated the emergence of this condition.

European brown hare syndrome virus (EBHSV) is related to RHDV and has occurred throughout Europe since the 1980s. Clinical signs are similar, with high adult mortality (90–100%); however, the viruses do not cross host species and spread independently.

Antigen structure of the viruses

Many caliciviruses (especially human viruses) cannot be grown in culture, and conventional serotyping is impossible. Noncultivable viruses have been typed by ELISA, immunoelectron microscopy (IEM) or solid phase IEM (SPIEM) and both type-specific and common epitopes exist. However, reagents have been limited and independent classification schemes have been devised. These should be unified now that recombinant antigens are available.

FCV and RHDV/EBHSV are the best understood. The single structural protein is the major antigen for all viruses. In FCV neutralizing antibodies bind to a highly variable region of the capsid protein in the C-terminal half of the protein, which is presumably exposed on the virus surface. This region is bisected by a conserved sequence of 20 amino acids which may contribute to the cell-binding site, and antibodies binding here may prevent attachment; variability in this region could allow FCV to evade immune control. Nonneutralizing antibodies bind elsewhere. RHDV and EBHSV strains are well conserved and so potentially variable regions cannot be identified. However, most monoclonal antibodies (including those which are protective) also recognize

the C terminal half of the protein. Such antibodies tend to be specific for RHDV or EBHSV and react poorly with smooth particles which lack the surface projections. Conversely, antibodies recognizing smooth particles tend not to be protective and react with both RHDV and EBHSV. Thus the antigenically distinctive surface structure of the virus is probably formed by the C-terminal of the protein, while underlying structures are similar.

Immune responses of the host

Feline calicivirus

FCV infection causes transient lymphopenia and neutrophilia, but cats may also be infected with feline immunodeficiency virus (FIV), which also decreases lymphocyte number and immune response. Thus coinfection with FCV and FIV increases the clinical severity of infection. However, FIV has no effect on the period of FCV shedding and is not important in the establishment of persistent infections.

Persistently infected cats mount both cell-mediated and humoral immune responses but fail to clear the virus promptly. The reasons for this are unknown. The tonsils are the major site of persistence but tonsillectomy does not cure the infection and other lymphoid tissue may be involved; feline T lymphoblastoid cell lines have been persistently infected with FCV. Persistence may be lifelong but some studies imply a half-life of approximately 75 days, with animals spontaneously eliminating the virus.

Human caliciviruses

Seroprevalence studies still reflect the previous distinction between the typical caliciviruses and SRSVs (above). Exposure to one of these forms (SRSVs in particular) may induce antibody which cross-reacts with other viruses of the same form (i.e. other SRSVs). These cross-reactions may be one-way (presumably because the immunogenicity of certain epitopes is sometimes functionally masked). Thus a fourfold rise in antibody titer is not sufficient for diagnostic purposes, and an eightfold rise may be preferable; alternatively IgA is more type specific.

Reinfection by NV is believed to be common; surprisingly, pre-existing antibody (secretory or serum) has been correlated with susceptibility to illness. Recovery was associated with an antibody rise, but many volunteers were soon susceptible, becoming ill again on rechallenge. Thus adults may differ in susceptibility to NV – sensitive individuals being protected only by high titers acquired after several infections; however, other studies have not confirmed this correlation.

In Scandinavian countries, infection occurs early in childhood but adults are protected. Thus age at first exposure could be relevant to protection in adults. Swedish children soon develop immunoglobulin G1 (IgG1) responses to NV, but persons over 21 years old also showed NV-specific immunoglobulin G4 (IgG4), indicating repeated exposure, but it is not known how often this was associated with illness. Immunity to these agents thus requires more investigation.

In contrast, antibody to the morphologically typical HuCV is protective and mainly type specific. Antibodies to HuCV/Sapporo were detected in 65% of Japanese children aged 2–5 years and in 90% of those aged 6–12 years. A second virus, UK1, also circulates in Japan and 69% of children aged 6–12 years had antibodies to both viruses. Both viruses are probably distributed worldwide.

Evasive strategies of the virus

The FCV capsid protein is known to be variable (above). FCV comprises a single serotype but variation is such that sequential infection by antigenic variants is possible. During infection (persistent or acute), the antigenic profile of the virus may drift; virus isolated later in infection may be more vaccine resistant. This drift may allow the virus to resist herd immunity. It may also affect pathology by influencing host tissue range; for example, enteric forms of FCV resist bile salts, while respiratory forms do not. However, bile-resistant variants can be selected from bile-sensitive populations. Monoclonal antibodies may differentiate between strains associated with different clinical presentations, implying that some determinants of pathology may be close to antigenic regions.

Vaccines

Vaccines are available for FCV and RHDV. The FCV vaccine is based on a live virus, using a single strain (F9), chosen for low pathogenicity and cross-reactivity; it induces neutralizing antibody to approximately 50% of field strains. Protection is probably wider, as non-neutralizing antibody can protect *in vivo*. Recently FCV field strains have changed; this may reflect natural variation, but the effects of widespread vaccination with a strain of restricted antigenicity cannot be ruled out. These changes have not yet undermined the usefulness of F9 as a vaccine. Vaccine 'failure' is probably due to inadvertent vaccination of cats already incubating the virus after natural infection. Isolates obtained from postvaccination complications are not normally vaccine

related, but are usually wild-type strains, susceptible to neutralization by vaccine-induced antibody. Multivalent vaccines may be required in future because low levels of antibodies to different strains give better neutralization than high levels of antibody to just one. Vaccination neither prevents nor cures a persistent infection.

The RHDV vaccine is made from virulent virus grown in rabbits and inactivated; it is effective but difficult to manufacture. The recently characterized nonpathogenic form of RHDV may be a suitable live vaccine if cultivation problems can be solved. Recently, recombinant virus-like particles (VLPs) have been developed for RHDV and are effective immunogens. VLPs have also been made for some of the human caliciviruses (e.g. NV and HV) but these have yet to be proven as vaccines.

CAMPATH-1 ANTIGEN (CD52)

Geoff Hale, Sir William Dunn School of Pathology, University of Oxford, Oxford, UK

The CD52 antigen of human lymphocytes was first defined with monoclonal antibodies isolated in the Department of Pathology, University of Cambridge. It is a lipid-anchored glycoprotein, unusual in having an extremely small peptide component. CD52 antibodies are remarkably lytic, killing cells *in vitro* with human complement, and also *in vivo*, probably by

other mechanisms. They have many possible applications for therapy, for example in treatment of leukemia, bone marrow transplantation, organ transplantation, rheumatoid arthritis, vasculitis and multiple sclerosis.

Figure 1 Primary structure of the CD52 antigen, showing the large N-linked carbohydrate, the small peptide and the glycosylphosphatidylinositol anchor. (Reproduced with permission from Treumann *et al.* (1995).)

Monoclonal antibodies

Many CD52 antibodies have been generated including different rat isotypes (e.g. CAMPATH-1M, rat immunoglobulin M (IgM) and CAMPATH-1G, rat IgG2b), matched sets of chimeric human/rat IgG and a variety of mutants. These have been used to demonstrate the role of IgG isotype for complement activation and Fc receptor binding, showing that rat IgG2b and human IgG1 are among the best subclasses for activating human effector systems. However, even human IgG4 (previously thought to be inert) was able to deplete human lymphocytes *in vivo*. CAMPATH-1H (human IgG1) was the first fully humanized monoclonal antibody. It was created by transplantation of the complementarity-determining regions of CAMPATH-1G into human heavy and light chain genes. Initial binding affinity was diminished, but this was corrected by small modifications to framework residues. Administration of the humanized antibody to patients has greatly reduced the possible antiglobulin response, compared with the original rat antibody. Following this experience, most other therapeutic antibodies are likely to be humanized.

Antigen structure

The CD52 antigen is well defined at a genetic and structural level, but its function is currently unknown. Encoded by a single gene on chromosome 1, it is a remarkably small glycoprotein, having only 12 amino acids (Figure 1). Attached to Asn3 is a complex carbohydrate consisting of sialylated polylactosamine units with a tetra-antennary fucosylated mannose core. At the C-terminus is a glycosylphosphatidylinositol (GPI) anchor. The CAMPATH-1 epitope includes the C-terminal amino acids and part of the GPI anchor. This implies that the antibodies bind close to the cell membrane, which explains why they are so good for cell lysis. Other antigens with a similar structure to CD52 include CD24 and its mouse homologue J5 (heat-stable antigen).

(A)

(B)

Figure 3 Treatment of polymphocytic leukemia with CAMPATH-1H. Complete clearance of tumor cells from blood and bone marrow was achieved, together with substantial reduction in the mass of tumor in the spleen, as shown by these computed tomograms taken (A) before and (B) after therapy. In total it was estimated that approx 4 kg of tumor was cleared by 126 mg of antibody. (Reproduced with permission from Hale *et al.* (1988).)

Tissue distribution

The distribution of the CD52 antigen is one of its most distinctive features. In humans the antigen is abundantly expressed on virtually all lymphocytes at most stages of differentiation (except plasma cells)

Human	GQ-----NDTS-----QTSSPS
Monkey	SQ-----NATS-----QSSPS
Mouse	GQATTAASGTINKNSFS-----TKKTP LKS
Rat	GQ-----NSTAVTTPANKAATTAAATTCAAATTATKTTTAVRKT PGK
Dog	G-----NST-----PRMTTKKVK SATPA

Figure 2 Comparison of CD52 protein sequences from different species showing the diversity of the mature sequences. Signal peptides (not shown) are much more similar. The human peptide has a single *N*-linked oligosaccharide. The rat peptide (SMemG) probably has, in addition, up to 14 *O*-linked oligosaccharides attached to the various Thr residues.

and also on monocytes, macrophages and eosinophils. T cells have approximately 450 000 molecules per cell. The antigen is not found on any other tissues except the male reproductive tract, where it is expressed very strongly on epithelial cells lining the epididymis, vas deferens and seminal vesicle. Antigen is shed from these cells in large quantities into seminal plasma, where it exists in small micellar particles and in larger membrane-bound structures called prostasomes. From these, it can be transferred to other cells, particularly spermatozoa. The CD52 antigen, along with other GPI-anchored antigens such as CD55 and CD59, is a major membrane protein of sperm, acquired during maturation. It is a matter of speculation whether transfer of GPI-anchored molecules from one cell to another is of more general physiological significance. Genes homologous to human CD52 have been described in monkey, dog, rat and mouse. They are all expressed in the male reproductive tissues and (where tested) in lymphocytes. Although the genes have substantial homology in the nontranslated regions and signal peptides, the short mature peptides are quite different (Figure 2).

Antibodies in therapy

CAMPATH-1 antibodies have been used in a variety of clinical trials. The IgM antibody, CAMPATH-1M, was developed for prevention of graft-versus-host disease by depletion of donor T cells from bone marrow. This was very effective, but resulted in an increased risk of graft rejection and of leukemia relapse. Now CAMPATH-1G or CAMPATH-1H are being tested for simultaneous control of both donor and host T cells, with a proportion of donor T cells being kept for later administration in the event of leukemia recurrence. CAMPATH-1H has been used for treatment of lymphoid malignancies and was very effective in patients with certain leukemias (T cell prolymphocytic leukemia and B chronic lymphocytic leukemia), but less so in patients with solid tumor masses (Figure 3). It has also been used as an immunosuppressive agent for treatment of transplant rejection and autoimmune diseases, including rheumatoid arthritis, vasculitis and multiple sclerosis (Figure 4). Treatment resulted in longlasting lymphopenia, particularly of CD4⁺ cells, which may not

Figure 4 Treatment of Wegener's granulomatosis with CAMPATH-1H. This patient suffered from severe erosion of sinus passages due to leukocyte infiltration, as shown by whole body scanning after injection of ¹¹¹In-labeled leukocytes (area circled). Antibody treatment depleted the T cells which were driving the inflammatory process and this resulted in a normal leukocyte scan and disease stabilization for at least 12 months. (Reproduced with permission from Reuter *et al.* (1995).)

return to normal blood levels for several years. The immunological significance of this is not obvious as few, if any, of the patients appear to suffer any long-term immunodeficiency. The majority of patients experienced an improvement in symptoms (in the case of multiple sclerosis, a decline in the frequency of new lesions) which lasted from 2 months to over a year. In the event of relapse, retreatment was possible and only infrequently limited by an anti-idiotypic response.

In a minority of patients, the first lymphocytes to regenerate lacked GPI-anchored proteins. This is characteristic of cells in paroxysmal nocturnal hemoglobinuria (PNH) and probably results from a somatic mutation in the X-linked PIG-A gene which codes for a critical step in GPI biosynthesis. Considering the frequency and time course of appearance of these cells, it seems unlikely that a mutation was induced by therapy, rather that it selected GPI-deficient cells already present at low numbers. So far, these cells appear to have normal functions and may even mediate graft rejection. Patients do not appear to suffer any adverse effect and in due course they are replaced by normal lymphocytes.

Conclusion

The CD52 antigen is an unusual molecule which provides a model for studying the role of carbohydrate and GPI anchors in immune and reproductive systems. The lytic ability of CD52 antibodies *in vivo* raises many possibilities for therapy and for study of the role of lymphocytes in different diseases.

CAMPYLOBACTER, INFECTION AND IMMUNITY

Diane G Newell, Central Veterinary Laboratory, Weybridge, UK

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Characteristics of the organism and its antigens

The *Campylobacter* genus comprises several species of gram-negative, highly motile, bacteria with an S-shaped morphology and microaerobic growth requirements. Clinically the most important *Campylobacter* species are the thermophilic organisms, *C. jejuni* and *C. coli*, which colonize and invade the small intestine and colon and are the most common cause of human acute bacterial enteritis. Asymptomatic infection is common in underdeveloped countries but in susceptible patients diarrhea occurs, usually 3 days after infection, and lasts 2–3 days, although excretion may continue for several weeks. The mechanisms by which these campylobacters cause enteritis are, as yet, unknown but may involve adherence, invasion and/or toxin production. Several other *Campylobacter* species, including *C. lari*, *C. hyointestinalis*, *C. concisus* and *C. upsaliensis* have also been implicated as causative agents of enteritis. All these enteric campylobacters may also cause blood and systemic infections. *C. fetus* subsp. *fetus* usually causes opportunistic septicemic infections in humans. Campylobacteriosis is generally self-limiting but arthritis and glomerulonephritis are not uncommon reactive complications and about 50% of cases of Guillain-Barré syndrome are thought to be associated with a prior *C. jejuni* infection.

In the following text the term 'campylobacter' will refer to the *C. jejuni/coli* group of organisms unless otherwise stated. The strains in this group are diverse and two serotyping schemes have been developed for use in epidemiologic tracing. The Lior serotyping scheme is based on heat-labile antigens and utilizes slide agglutination of live bacteria with serotype-specific rabbit antisera preabsorbed with homologous heated and heterologous unheated cross-reactive antigens. Flagellin is considered to be one of the antigens involved in this serotyping scheme. The Penner serotyping scheme is based on heat-stable antigens and involves the passive hemagglutination of erythrocytes, sensitized with boiled saline bacterial extracts, by serotype-specific rabbit sera. Lipopolysaccharides (LPSs) are thought to be the dominant heat-stable antigen involved in this scheme.

Several surface protein antigens of the campylobacters have been described. The most well charac-

terized antigens are the flagellins. The campylobacters have single, bipolar flagella. In animal models using isogenic mutants fully active flagella are essential virulence factors. There are two flagellin genes (*flaA* and *flaB*) in tandem in all strains, although only one of these genes may be expressed. The flagellins have a molecular weight of approximately 62 kDa and are the major protein surface antigen. The antigenicity of campylobacter flagellin is complex and epitopic analysis indicates that common as well as serotype-specific linear epitopes are expressed. The common epitopes are antigenically cross-reactive with flagellins from most *Campylobacter* species, including *C. fetus fetus*, *C. lari* and *Helicobacter pylori* (formerly *C. pylori*). Antigenic variations occur between these flagellins, and a microheterogeneity in charge properties due to post-translational modification, probably glycosylation, also demonstrates some antigenic variation. Additionally there is a reversible transition between flagellated and aflagellated variants.

There are several other conserved groups of protein antigens. The variable molecular weight (42–47 kDa) major outer membrane protein (MOMP) is surface exposed. The antigenicity of this protein mainly relies on its native conformation and it is antigenically cross-reactive with similar proteins in *C. coli* and *C. lari* but not other *Campylobacter* species. A group of surface extractable antigens (26–32 kDa), called the PEB proteins (PEB 1–4), have been isolated and partly characterized. PEB 1 has been cloned and sequenced and may have adherence properties. Some of the campylobacters produce detectable toxins, one of which has some antigenic cross-reactivity with cholera toxin, but is structurally different, comprising a 66 kDa polypeptide, probably a holotoxin, and a series of antigenically related subunits. Recently the expression of pili on *C. jejuni* has been described but the role of these structures in pathogenicity has yet to be determined.

Immune response of the host

Patients with campylobacter enteritis produce a rapid circulating antibody response. These antibodies have complement fixing, bactericidal and agglutinating properties. The initial specific immunoglobulin M (IgM) response is produced by the 8th

day of infection and is relatively short lived. This is followed by a rapid serum polymeric and monomeric IgA response, which peaks at about 2 weeks after onset of symptoms but disappears by the 5th week. The IgG antibodies are detectable within 10 days of the illness and persist for several months. The short illness generally associated with campylobacter enteritis suggests that these antibodies are effective at limiting infection. The antibody responses form the basis of a serologic test for the retrospective diagnosis of infection using ELISA, with an acid-extractable surface antigen which primarily comprises flagellin.

Analysis of the antigenic specificity of the host immune responses shows that the immunodominant surface antigen is flagellin. Antibodies directed against this polypeptide are produced early in infection and may be protective. The MOMP is also immunogenic, during infection, in most patients. When present all these antibodies react against homologous and heterologous strains. LPSs appear to induce inconsistent antibody responses, which when present may be serotype specific.

Guillain-Barré syndrome is characterized by acute motor neuropathy, which appears to be a sequela of campylobacter enteritis in about 50% of cases. Many patients with this disease have increased circulating IgG and IgM antibodies binding to GM1 and GD1 ganglioside epitopes and which cross-react with LPS of certain serotypes of *C. jejuni*, especially types O:19 and O:4.

To date, T cell responses to the campylobacters have been poorly investigated.

Evasive strategies by the organism

No mechanism by which *C. jejuni/coli* evade the host immune response has been identified; however, in some experimental models virulence is associated with persistence in the bloodstream, survival in extraintestinal organs and resistance to macrophage ingestion. One potential mechanism for bacterial avoidance of host immune responses could be antigenic variation of the flagellin proteins.

C. fetus fetus has a well-defined microcapsule, comprising surface array proteins (S-layer proteins), which is responsible for resistance to the complement-mediated bactericidal activity of normal human serum and phagocytosis by polymorphonuclear cells. These S-layer proteins, which form a crystalline subunit structure on the outer surface of the bacterium, have a range of molecular weights (97–149 kDa) and are encoded by about eight homo-

logs of the *sapA* gene. The S-layer proteins are highly immunogenic during infection. There is significant antigenic variation between each of these proteins, and antigenic switching occurs throughout infection, apparently enabling the persistence of this organism in host tissues.

Vaccines

The evidence suggesting that protective immune responses can be produced after campylobacter infection includes: a progressive decrease in the illness:infection ratio in children from underdeveloped countries with endemic infections; high antibody levels and asymptomatic infections after multiple exposures to campylobacter-contaminated food-stuffs; and the development of protective immunity to rechallenge in experimentally infected volunteers and nonhuman primates. Passive immunization may also be effective as campylobacter-specific sIgA antibodies in breast milk apparently protects infants from disease. These sIgA antibodies are primarily directed against flagellin. Epidemiologic evidence suggests that protective immunity controls the symptoms of disease but does not necessarily prevent intestinal colonization.

Vaccines against campylobacter enteritis are currently under development. A killed whole-cell vaccine induces protection in a mouse model using the heat-labile toxin of *Escherichia coli* (LT) as the mucosal adjuvant. The same vaccine has been successfully tested for safety and immunogenicity in nonhuman primates. Potential candidates for subunit vaccines include the flagellins and other surface acid-extractable proteins.

CANDIDA, INFECTION AND IMMUNITY

David K Wagner and Peter G Sohnle, VA Medical Center, Milwaukee, Wisconsin, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Characteristics of the organism and its antigens

Infections due to organisms in the genus *Candida* are relatively common, with a variety of different manifestations of disease in both humans and animals. These organisms all grow as yeast and most of the individual species also have filamentous forms, which are either pseudohyphae or true hyphae. There are over 150 species of *Candida*, but only 10 are significant pathogens for humans. These species include: *C. albicans*, *C. glabrata* (formerly *Torulopsis glabrata*), *C. parapsilosis*, *C. krusei*, *C. guilliermondii*, *C. Stellatoidea* (now considered *C. albicans*), *C. tropicalis*, *C. pseudotropicalis*, *C. lusitaniae* and *C. rugosa*. Of these, *C. albicans* is the primary pathogen for humans.

Candida can produce a wide variety of human infections that can be generally divided into superficial and deep infections. Superficial *Candida* infections involve skin, nails or mucous membranes of the mouth and vagina. Deep *Candida* infections include candidemia, localized infections of various deep tissues, and disseminated candidiasis in immunosuppressed patients. This classification is significant because the host defense mechanisms involved in the two groups of infections may be different. In particular, cell-mediated immunity is a primary host defense in superficial candidiasis, while neutrophils (and possibly macrophages) are important in deep candidiasis. Hence, patients with the acquired immune deficiency syndrome (AIDS) and its prominent T cell immune defect commonly have oral thrush, but usually do not have deep *Candida* infections. On the other hand, patients with hematologic and other malignancies who become neutropenic during chemotherapy are more at risk for deep *Candida* infections.

The antigens of these organisms are complex, and infected patients often respond to a number of cell wall, cell membrane or cytoplasmic components. The major cell surface antigen of *Candida* is mannan, a part of the cell wall. *C. albicans* isolates have been serotyped into two groups, A and B, by antigenic differences in their mannins. Cytoplasmic antigens of this organism have also been extensively studied for use in the diagnosis of *Candida* infections. Humoral immunity to a cytoplasmic antigen of approximately 50 kDa in patients with deep candidiasis has been described by a number of investigators. Unfortu-

nately, immunosuppressed patients at the highest risk of serious disease may not have an appropriate antibody response, and often have false-negative antibody levels. Also, because some patients with superficial *Candida* infections may develop a significant antibody response, the assays for humoral immunity to *Candida* antigens have not proven to be useful diagnostically. However, because an early clinical diagnosis of systemic *Candida* infection is frequently difficult, there is interest in other serologic tests. Testing for the presence of *Candida* cytoplasmic antigens has been described by multiple investigators. Unfortunately, this test has a high incidence of false negative results. It has been suggested that the antigen does not circulate or may not circulate in a detectable form. Other diagnostic tests more recently studied include amplification of *Candida* DNA by polymerase chain reaction (PCR). This assay can detect as few as 15 cells of *Candida* in clinical specimens, but its clinical utility remains to be determined.

Immune responses of the host

Candida species are found commonly in the environment, and can be recovered from the soil. They are normal flora in the human gastrointestinal tract, and can often be found at other mucosal sites and on diseased skin. The initial host defenses are the non-specific barriers including intact skin and mucosal epithelium, as well as the indigenous bacterial flora that competes for binding sites. Breakdown of these barrier functions, (e.g. from burns or indwelling intravascular devices) allows for invasive *Candida* infections. Once the organisms invade past the non-specific defenses, the major cellular mechanism against *Candida* infections is through neutrophils. These cells are capable of phagocytosing *Candida* spores as well as damaging the pseudohyphae. Intracellular killing appears to be primarily through oxidative mechanisms. Other cells of the immune system (monocytes and eosinophils) are also able to phagocytose and kill *Candida* organisms. Even so, the initial response in the tissues is predominantly by neutrophils, frequently with the formation of microabscesses in infected tissues. This response may be reduced in patients with significant impairment of host defenses, particularly in neutropenic patients or those on pharmacologic doses of corticosteroids. With more chronic infections the inflammatory

response usually becomes mononuclear. In cutaneous candidiasis, the organisms are generally confined to the stratum corneum; the resulting inflammatory response may be an epidermal accumulation of neutrophils in acute infections, or a dermal mononuclear cell response in more chronic infections. Both yeast and pseudohyphae are seen in infected tissues of both deep and superficial sites, although the filamentous forms are generally felt to be more characteristic of tissue invasion.

Because *C. albicans* is part of the normal gastrointestinal flora, the majority of normal human subjects will show evidence of prior sensitization to the antigens of this organism. Most people will have low levels of antibodies to *Candida* mannan. In infected patients, elevated levels of *Candida*-specific antibodies have been found, representing the IgG, IgM and IgA immunoglobulin classes. Elevated salivary IgA levels have also been demonstrated in response to *Candida* stomatitis, and IgA levels against this organism have been found in vaginal secretions. In addition, patients with either allergic respiratory diseases or the hyper IgE syndrome have been demonstrated to have elevated levels of IgE antibodies specific for *Candida*. Whereas antibody titers to *Candida* are usually elevated in infected patients, the humoral immune response does not appear to play a major role in host defense against *Candida*. It has been shown, for instance, that serum and plasma alone (containing antibodies and complement) are not able to kill *Candida* organisms.

In addition to making antibodies, most people will also demonstrate delayed hypersensitivity to *Candida* antigens when subjected to skin testing with extracts of this organism. As described above, patients with defects in cell-mediated immunity are at higher risk for superficial *Candida* infections. This finding is especially apparent in conditions such as AIDS and in the condition known as chronic mucocutaneous candidiasis. AIDS patients are commonly afflicted with recurrent oral *Candida* infections. Patients with chronic mucocutaneous candidiasis have long-lasting and often disfiguring superficial candidiasis without obvious predisposing causes. Endocrinopathies, thymomas, vitiligo, alopecia, and a tendency to develop other types of infections are found in some of these patients. A variety of immunologic abnormalities have been described in this condition, but of these, defective cell-mediated immunity to *Candida* antigens, as manifested by negative delayed hypersensitivity skin tests and abnormal *in vitro* assays of lymphocyte function, have been found most consistently. In contrast, patients at risk for deep candidiasis usually have other types of predisposing factors such as neutro-

penia, steroid therapy, indwelling vascular devices, broad-spectrum antibiotic therapy, and the like. Some of these factors may also enhance the patient's susceptibility to superficial candidiasis as well.

Evasive strategies by the organism

Adhesion is an important initial step in infection of epithelial or mucosal sites. In this regard, *Candida* organisms have been shown to express three types of adhesion molecules. After adhesion of the organisms, other potentially important virulence factors of *Candida* which may assist in promoting invasive disease include lytic enzymes, hyphal formation, and contact sensing. One lytic enzyme, an aspartyl proteinase, may assist penetration into the stratum corneum. Another enzyme, a keratinase, allows invading organisms to use keratin as a source of nutrients. Hyphal formation appears to be useful both in establishing colonization of surfaces and in tissue invasion but may not be absolutely essential for invasion. Contact sensing (also called thigmotropism), may also be a possible mechanism by which *Candida* organisms distribute and align themselves in order to penetrate surfaces.

Infection of superficial sites such as the skin, mucous membranes and nails may also be a method by which *Candida* organisms can avoid a vigorous inflammatory response. In acute infection, neutrophils do seem to be able to reach the site in the stratum corneum where the organisms reside; however, in chronic mucocutaneous candidiasis this infiltrate is generally not present, and the mononuclear infiltrate which does occur is usually confined to the dermis and is therefore not directly in contact with the organisms.

As discussed above, neutrophils appear to be a very important component of the host's defense against *Candida* invasion into deep tissues. These cells are capable of ingesting and killing *C. albicans* yeast cells *in vitro*; however, unkilld yeast cells have also been observed to germinate within neutrophils and perforate through the cell membrane to the outside of the cell. More virulent strains of *C. albicans* have been demonstrated in one study to be relatively resistant to intracellular killing by human or mouse neutrophils, perhaps because they form germ tubes more rapidly than do less virulent strains. Therefore, germination to the filamentous hyphal or pseudohyphal forms may be a mechanism by which this organism can avoid killing by phagocytic cells. In addition, the filamentous forms of *C. albicans* have been shown to release a soluble product which inhibits chemotaxis, adherence, iodination of ingested particles, and superoxide production.

Vaccines

Studies with experimental animals have shown that vaccination with *C. albicans* preparations containing cell surface antigens can be protective when the animals were challenged with *Candida* organisms. However, as described above, most normal human subjects show both humoral and cell-mediated immunity to *Candida* antigens in the absence of preceding vaccination or known infection. Because lack of exposure to the organism does not appear to be involved in the susceptibility of humans to *Candida* infections (i.e. *Candida* is an opportunistic pathogen) vaccination is unlikely to be an effective method for preventing these infections.

CANINE IMMUNE SYSTEM

Tom R Phillips, Department of Neuropharmacology, The Scripps Research Institute, La Jolla, CA, USA

The canine immune system is just as impressive in its complexity and diversity as are the more thoroughly studied murine and human immune systems. Relative to most species, a large body of knowledge has accumulated about the canine immune system. This knowledge has arisen largely because of the importance of the dog as both a companion animal and transplantation model. Although this entry will primarily concentrate on the differences between the canine immune system and the immune systems of the more thoroughly studied species, it is important to note that the overall structural and functional organization of the canine immune system closely resembles its murine and human counterparts and that there are more similarities than there are differences.

Ontogeny

The gestation period of the dog is approximately 63 days. As with other animals, the stem cells of the immune system are believed to originate in the yolk sac. After a few weeks of gestation, the fetal liver and later the bone marrow become the primary source of these undifferentiated cells. The fetal thymus is apparent by the 28th day of gestation. However, it is not until 35 days postconception that precursor T cells are found in this organ. The ability to reject skin allografts first develops on day 40 of gestation, whereas antibody responses to sheep red blood cells cannot be elicited until the 48th day. Splenic lymphocytes first respond to phytohemagglutinin (PHA) on day 45. However, thymocytes do not develop this ability until gestation day 48. It is not until the second day after birth that peripheral blood lymphocytes respond effectively to PHA. Furthermore, this response does not peak until the puppy is at least 6

weeks old. Thus, the canine immune system develops late and is not fully mature at birth. This, in part, explains the importance of maternal immunity.

Maternal immunity

Maternal immunity, a form of passive immunity, plays a vital role for the neonate. It helps to protect the neonate during the critical transition from the protected uterine environment of the fetus to the hostile external environment of the newborn. Not only does this transition occur at a time when the neonate's immune system is not fully developed but also at a time when the neonate's immune system is naive to virtually all pathogens. Without the acquisition of maternal immunity, the survival of the neonate is greatly reduced. However, maternal immunity is not without its negative effects. It often interferes with active immunization, and is the most common cause of vaccine failure in the dog.

Rodents and primates obtain most of their maternal immunity by placental transfer, whereas dogs obtain the majority of their maternal immunity via colostrum transfer. Dogs have an endotheliochoral placenta. With this type of placenta, the fetal and maternal circulation are separated by four tissue layers: 1) the maternal capillary endothelium, 2) the chorionic epithelium, 3) the fetal connective tissue, and 4) the fetal capillary endothelium. In the hemochorial placenta, the placenta of primates and rodents, the maternal capillary endothelial layer is not present. With this latter type of placenta, the maternal blood actually bathes the fetal placental tissues. Because of the close approximation of the maternal and fetal circulation in the hemochorial placenta, maternal immunoglobulin G (IgG) is efficiently transferred to the fetus. Thus, approximately 75% of the primate and rodent maternal immunity is conveyed by placental transfer. In contrast, in the dog only 25% of the maternal immunity is transferred by this process, the additional placental layer being largely responsible for the decreased placental transfer of IgG.

The ingestion of colostrum during the first 24 h of life is responsible for the transfer of the remaining maternal immunity. Colostrum is the first secretion of the mammary gland after parturition and contains a high concentration of immunoglobulins. Within the first 24 h of life, the gastrointestinal system of the neonate is not fully functional. During this time, protein digestion does not occur. Thus, the immunoglobulins within the colostrum are not digested and remain intact as they pass through the digestive tract of the neonate. Additionally, the intestinal epithelial cells at this time are actively transporting proteins,

including the intact colostral immunoglobulins, through the intestinal wall of the neonate. Once the immunoglobulins are transported through the intestinal epithelium, they are taken up by the lymph system and eventually reach the general circulation. Colostral intake is particularly important to the dog, since 75% of its maternal immunity is derived via this route. The degree and duration of the dog's maternal immunity is largely dependent on the following factors: the amount of colostrum produced, immunoglobulin content of the colostrum, the amount of colostrum ingested, the age of the neonate at the time of colostral ingestion, and the size and growth rate of the neonate.

Natural resistance

The dog, like most multicellular organisms, has a vast array of defense mechanisms. Some of the most effective defense mechanisms are not part of the immune system but are classified as natural resistance. Natural resistance is defined as defense mechanisms which prevent or combat disease-causing agents by nonimmunologic means (without memory or specificity). Examples of canine natural resistance are barriers (skin, mucous membranes), commensal organisms (normal bacterial and viral flora), mechanical action (mucociliary tree, coughing, and desquamation), flushing action (urine, saliva, tears, milk and diarrhea), chemical and enzymatic action (gastric acid, digestive enzymes, lysozyme, and complement), nonspecific phagocytosis (macrophages and polymorphonuclear neutrophils), hormonal (α and β interferon), iron-chelating agents (lactoferrin), and natural killer cells. Although the dog does not have unique natural resistance mechanisms, it is important to understand the role of natural resistance in aiding the canine immune system. Natural resistance is the first line of defense against disease. Without natural resistance, the immune system would be overwhelmed and the dog or any other organism could not survive. It is only when natural resistance fails to prevent or eliminate disease-causing agents that the immune system has a role in disease control.

Humoral immunity

The immunoglobulin composition of the dog consists of the isotypes IgM, IgG, IgA, and IgE. Each of the canine isotypes serves the same basic function as the corresponding murine and human isotype. In a primary antibody response, IgM is the first and the most abundant immunoglobulin isotype produced. IgM is a pentameric molecule and, on a molar basis, is the

most efficient isotype in complement fixation, opsonization and agglutination reactions.

The immunoglobulin isotype with the highest concentration in blood is IgG, which has a higher affinity for antigen than does IgM. IgG, a monomeric molecule, can also participate in complement fixation, opsonization and agglutination reactions, although relative to IgM more molecules of IgG are required. Canine IgG has four subtypes, identified as IgG1, IgG2, IgG3, IgG4.

Usually found as a dimer, IgA is the most important isotype in canine mucosal immunity. IgA is often produced by submucosal lymphocytes and transported to mucosal surfaces by epithelial lining cells. As it is transported through the epithelial cell, the IgA molecule acquires a secretory piece. This secretory piece, which is produced by the epithelial cell, protects the IgA molecule from proteolytic enzymes that are frequently found on mucosal surfaces. Although IgA is the second most common isotype in human sera, it is only a minor component of canine sera. IgA agglutinates antigens but does not fix complement nor does it act as an opsonin. A major function of IgA is to prevent potential pathogens from adhering to or being absorbed by the various mucosal surfaces.

The canine serum concentration of free IgE is very low, the majority of IgE being bound to mast cells and basophils. Immediate hypersensitivity and systemic anaphylaxis reactions are mediated by vasoactive amines that are released when antigen cross-links mast cell-bound IgE. The most frequent form of immediate hypersensitivity in the dog is inhalant dermatitis, whereas immediate hypersensitivity usually involves the respiratory system in man. Another difference between the human and canine immune systems is the major anaphylaxis shock organ. In the dog, the shock organ is the liver; while in people it is the lung.

Cell-mediated immunity

Cell-mediated immunity in the dog, as in other species, is genetically restricted to class I and class II histocompatibility antigens. The major histocompatibility complex (MHC) of the dog, known as the dog leukocyte antigens (DLA), is less well characterized than the human or murine MHC. Three class I loci have thus far been identified in the dog: DLA-A (8 alleles), DLA-B (5 alleles), and DLA-C (4 alleles). For the canine class II loci, DRB, DQB and DPB genes have been identified. The class III MHC loci for the canine C4 has been identified. This locus codes for the fourth complement component of the dog.

Positive identification of the various canine T cell

subtypes has been hampered by the lack of appropriate reagents. However, recently two developments have helped to rectify this situation: 1) the production of monoclonal antibodies with reactivity to various canine T cell subtypes and 2) the recognition that some murine and human reagents cross-react with their canine homologs.

Canine cell-mediated immunity does not differ greatly from the murine and human systems. Antigen-processing cells, usually macrophage or dendritic cells, ingest the antigen, secrete interleukin 1 (IL-1) and present the various antigenic determinants on its surface in the contexts of the dog's MHC (class I or class II antigens). T helper cells, that have encountered IL-1 and recognize antigenic determinants complexed with the class II MHC, clonally expand and secrete various interleukins (e.g. IL-2, IL-4 and IL-5). Interleukins 2, 4 and 5 enable antigen-stimulated B cells to clonally expand and differentiate into plasma and memory cells. Additionally, IL-2 facilitates the differentiation and clonal expansion of cytotoxic T cells which have recognized antigenic determinants complexed primarily with class I MHC.

Natural killer (NK) cells, killer (K) cells, and T suppressor cells have also been identified in the dog. The NK cell of the dog is a large granular lymphocyte that directly kills viral-infected and cancerous cells in a nonimmune manner, without prior exposure to the antigen. In contrast, K cells kill their targets through antibody-dependent cellular cytotoxicity (ADCC). Macrophages, polymorphonuclear neutrophils, and some of the null (non-T non-B) lymphocytes can function as K cells. Genetically restricted T suppressor cells help to limit and control the canine immune response.

Pathologic alterations

There are numerous examples of inherited canine immunodeficiencies, which, not surprisingly, are often associated with a particular breed of dog. Canine cyclic hematopoiesis (gray collie syndrome) has been described in gray collies, pomeranians and cocker spaniels. With this condition, there is a cyclic fluctuation in the number of peripheral blood neutrophils, which, in turn, is associated with periodic bouts of bacterial infections. Although not a true immunodeficiency, Kartagener's syndrome, an absence of ciliary defense mechanisms, has been recognized in puppies with chronic respiratory disease. A selective IgA deficiency has been reported in beagles, doberman pinschers, German shepherd dogs, and shar-peis. A condition in weimaraners and bull terriers has been described, where the puppies

have an atrophied thymus, grow at a reduced rate and have a severely depressed lymphocyte response to mitogen. Severe combined immunodeficiency (SCID) in basset hounds and Cardigan Welsh corgis has been identified. Also, in Brittany spaniels, a C3 deficiency is associated with an increase in the number and severity of bacterial infections.

Acquired immunodeficiencies occur in a variety of conditions ranging from vitamin and mineral deficiencies (vitamin E and selenium) to viral and bacterial infections (neonatal canine distemper virus infection and severe staphylococcal pyoderma).

A variety of autoimmune conditions occur in the dog. These include but are not limited to autoimmune hemolytic anemia, thrombocytopenia, pemphigus, immune-complex glomerulonephritis, autoimmune thyroiditis, Sjögren's syndrome, rheumatoid arthritis and systemic lupus erythematosus. Anti-nuclear antibodies have been associated with the MHC gene DLA-12; and systemic lupus erythematosus is associated with MHC DLA-A7. An association with diabetes mellitus with DLA-B4 as well as DLA-A3, A7, and A10 has also been reported.

Evaluation of immunologic responsiveness

From the discussion of the canine immune system, it is clear that many similarities to the murine and human immune system are found. However, it is vital to realize that critical differences between these systems exist. It is tempting to directly apply a human or murine function test to assess the canine immune system. This direct application could yield erroneous results or interpretations. Often, all that is required is a minor alteration of the assay or its

interpretation to make the assay applicable to the canine immune system. Since it is beyond the scope of this entry to discuss each assay and their potential alterations, the reader is referred to the Further reading section for more information.

CAPPING, CLUSTERING, MEMBRANE MICRODOMAINS AND CELL SURFACE DYNAMICS

Francis Loor, Pharmacological and Biotechnological Research Center, University of Strasbourg, Illkirch, France

The discovery of membrane component mobility and redistribution (capping and clustering), by immunologists, some 25 years ago was a major breakthrough in cell surface science. It has also been a major step in the development of our understanding

of how the cell surface may have evolved and how it may work to transmit messages which are more complex than those mediated by the simple binding of a ligand to a receptor molecule. By contrast, cell-to-cell recognition is a phenomenon involving a co-

ordinated sequence of interactions of several different ligands and recognition elements on each cell partner. To fully achieve antigen presentation by one cell and antigen recognition by the other cell, there is a need for a reciprocal recognition of two-dimensional glycoprotein *patterns* which can be created only by the precise *topographical* rearrangements of membrane components within given *microdomains* of the plasma membranes of both interacting cells.

Capping

Capping phenomena have been described for a variety of membrane components in a variety of cell types. The basic model remains the polar capping of membrane immunoglobulins (mIg) on B lymphocytes by anti-immunoglobulin antibody. When different membrane components are successively capped, they migrate to the same cell pole. This pole is assigned to the cell by the zone of contact of its membrane either with another cell or with a substratum. The general characteristics of the capping phenomenon, particularly the energy requirements, temperature dependence, inhibition or reversion by microfilament-directed drugs (cytochalasins), and the accumulation of microfilaments under the cap, have led to the suggestion that capping is probably an active cellular contractile phenomenon. Early cell adhesion studies also suggested that the expression, distribution and dynamics of ligand recognizing domains might be controlled by the microfilamentous network of the cell. Ligand recognition may be followed by cell motility changes and by increased adhesion to a substratum or to other cells. As early as 1973, expression of adhesive sites by lymphocytes was also found to be an active cellular process, its linkage to microfilament dynamics being shown later. It is unclear, however, whether adhesion and capping may be mechanistically related to each other.

For capping to occur, contractile microfilaments drag *anchored* patches of *aggregated* membrane components into an area of the cell where they can be endocytosed and digested, or shed from the surface. As microtubules do not appear to enhance microfilament mobility but rather to inhibit it, their role in the capping phenomenon is more complex. When microtubules are depolymerized by exposing the cells to specific drugs (e.g. colchicine, *Vinca* alkaloids) or to a chilling shock, the capping occurs on the uropod of the cell. Shedding or endocytosis may, however, occur on the whole cell surface when microtubules interfere with the polar redistribution of clustered ligands and membrane components. Capping of any membrane component would occur as a consequence of entrapment of microfilament-

associated membrane anchors within the lattices or clusters formed on the plasma membrane. These microfilament-driven anchors would then sweep any aggregated membrane components or adsorbed material toward the cap area, a zone of high endocytotic activity. Both the membrane sites involved in intercellular adhesion and the membrane anchors involved in capping might be proteins of the integrin and cadherin families.

Clustering

Monomeric antigens, monovalent lectins and monovalent antibody to mIg or any other membrane component do not cap on the cell surface, nor do they form large clusters (spots or patches). Like capping, clustering requires multivalent ligand binding, but unlike capping it is a passive redistribution process: spotting/patching does not require the cell to be alive or metabolically active. It is actually best to observe clustering on cells whose capping machinery is inhibited either by specific drugs or as a consequence of a general inhibition of cellular metabolism. In the context of the original postulate of Singer and Nicolson for cell membrane organization as a 'fluid mosaic of proteins and lipids', the clustering of membrane components may be viewed as an immunoprecipitin reaction or a lectin-mediated aggregation occurring in a two-dimensional pattern at the level of the plasma membrane. Clustering should therefore be affected not only by all the factors that commonly control such phenomena occurring in a three-dimensional fluid aqueous phase (e.g. 'antigen' or 'antibody' excess in a precipitin reaction), but also by the physicochemical properties of the plasma membrane. Besides factors intrinsic to the lipid-bilayered membrane itself, the outcome of the cluster formation should also be influenced by physiological interactions between the membrane proteins themselves. While intermediate filaments, actin filaments and microtubules constitute the main skeleton of the cell and control its overall 'long-range' shape, a variety of both integral and peripheral membrane components may constitute a distinct but interacting skeleton in the submembranous peripheral cell cortex which would sustain the plasma membrane and may cause a 'mid-range' modulation of membrane component topography.

Colocalization

A method of 'differential redistribution' of membrane components into patches and caps has been broadly used to probe the possible interactions between various plasma membrane components, or

between the cell membrane and cytoplasmic structures. If two components A and B were stably associated in the membrane, the clustering and capping of A should always copatch and cocap B. If on the contrary, A and B were never associated, the clustering of one should not affect the distribution of the other. Obviously, since mIg epitopes and major histocompatibility complex (MHC) epitopes were not cocapped, it could be concluded that these were different and independent molecules. Similarly the myosin involvement in the contractile processing and removal of the aggregates from the cell surface was supported by it being found concentrated in the cytoplasmic cortex of the cell just beneath patches of membrane components aggregated by an external ligand.

A number of membrane and cytosolic components were studied in this way and showed 'colocalization'. This led to the discovery of a host of membrane skeletal proteins which may create complex networks of interacting components on and between both faces of the membrane. Similarly, interactions of antigen receptor complexes with proximally recruited CD membrane components in the plasma membrane plane eventually lead to three-dimensional scaffolds of cytosolic protein tyrosine kinases and phosphatases and adaptor proteins as transducer units.

Such differential redistribution studies have a variety of potential pitfalls. Indeed, besides the two aforementioned, simple cases, there were a variety of alternate forms of incomplete and/or unidirectional interactions, three of which are suggested hereafter. 1) Although A and B are molecularly independent, ligand binding might cause conformational changes in A, which then allows binding of A to B, so that capping of A may lead to cocapping of B, whereas the interaction of B with its ligand would not bring A in the cap ('syn-capping'). 2) If there is a large excess of one membrane component over another, a massive aggregation and capping of the major component might entrap the minor one and bring it into the cap, even though the two types of components never showed any affinity for each other during this 'mass effect'. 3) Ligand binding might also trigger a complement-like 'cascade reaction' on the cell surface which may involve several membrane components, both integral proteins and peripheral membrane components in the glycocalyx and in the cytosolic membrane skeleton.

Although such colocalization studies may show that a variety of integral and peripheral membrane components do easily interact with each other, they may not always indicate whether there was *prior colocalization* or whether there has been *recruitment*. They say little about the natural status of distri-

bution of such components in a 'resting' cell. To evaluate membrane component interactions, e.g. to determine whether various membrane components constitute homodimers, heteropolymers or large complexes of several different molecules, instantaneous ('pulse') nearest-neighbor-type biochemical studies of the membrane of cells, both resting and in different activated status, are more suitable than patching and capping.

In addition to these restrictions, the possible isomeric forms of some membrane proteins should also be taken into account; the most representative cases are those of proteins which may exist as two widely different membrane forms, either with a classical transmembrane polypeptide anchor ('TM proteins') or with a glycosylphosphatidylinositol anchor (GPI proteins'), and which may show different physicochemical and/or physiological relationships with other molecular partners in *cis* on the membrane. Moreover, the hypothesis has been formulated that not only ligand-clustered components but rather whole *microdomains* of plasma membrane (including unliganded components) might be brought into the cap. This concept puts severe restrictions on the use of capping as a means of *selective* removal of given membrane components from the plasma membrane.

Finally, it is unclear whether any membrane component may be capped by clustering ligands, and there is also no evidence that all types of membrane component redistributions reported as 'caps' actually proceed through a unique mechanism. Even though the caps were made on the same cell pole and mediated by actin filaments, capping may involve anchorage through integrins for some membrane components, but through cadherins for some others, whereas some 'caps' may actually represent a polar redistribution of microvilli, or a passive recruitment of all clusters into a single one. If whole membrane microdomains rather than individual components show polar redistribution, cocapping may simply reflect the fact that the capped components belong to the same type of domain, whereas independent capping would show they are in different domains, and further conclusions on physical interactions of components with each other are probably speculative.

Capping as a sign of leukocyte polarization?

A misinterpretation of the Singer-Nicolson model of biological membranes would be that the entire cell surface was organized as a continuous fluid mosaic of proteins and lipids without any short-, mid- or long-range order. Obviously, this could not hold true

for highly polarized cells. The epithelial cell represents the most straightforward case for a *segregation* of the whole cell surface as large domains, the apical membrane and the basolateral membranes not only showing widely different protein, lipid and carbohydrate compositions but also being sustained by different types of submembranous skeletons and controlled by different sets of deeper cytoskeletal networks.

Of greater concern in immunology are the domains with the ligand recognition-coupled transduction signals. Would the plasma membrane of the round and resting leukocyte also show segregation of its components as multiple microdomains? Would their polarized redistribution on the leukocyte, when it develops a prominent uropod, possibly mimic the epithelial cell model? Effective triggering through ligand-recognizing domains is usually coupled to changes in cell motility. Moreover, one of the most prominent responses of lymphocytes to recognition of their ligands is an increased adhesion, through tangles of microvilli, either distributed all over the cell surface or redistributed to the uropod, such as observed when various types of killer cells bind to their targets, when lymphocytes interact with macrophages, when leukocytes bind to vascular endothelium for migrating into tissues, when T cells form rosettes with red cells, and when lymphocytes form aggregates either spontaneous or induced by ligands or mitogens.

Membrane component freedom

Most *functional antigen-receptor units* on the lymphoid cell surface are 'receptor complexes' which are constituted by several interacting subunits, some endowed with a recognition function (ligand binding), some responsible for effector function (cytoplasmic signaling) and some having a conveying function (linker, transducer). Thus, in 'resting', i.e. non-activated conditions, a cell surface may show the existence of discrete microdomains, with a short- to mid-range order organization of selected membrane components. Most such receptor complexes might not be under the 'permanently assembled' form, however – nature would not have missed such a key regulatory mechanism and a good occasion to create a host of variants. Rather, components of receptor complexes must be in a continuous equilibrium of association and dissociation, being regulated both by the intracellular, physiological status of the cell and by its extracellular, environmental context. Such regulation of receptor complex assembly needs not to be exclusively occurring at the level of the integral elements which are directly anchored within the lipid

bilayer itself; it may also be mediated by peripheral membrane elements which belong to the outer cell surface, such as components of the glycocalix, and to the inner cell surface, such as components of the membrane skeleton.

If they do not permanently form covalent or non-covalent complexes, the dissociated elements of the receptor complexes must find each other. Membrane fluidity would be a disadvantage if such elements which need to interact reversibly with each other could diffuse on the whole cell surface. Therefore, lateral diffusion of the membrane proteins should be restricted in fluid membranes in order to allow the coupling in a two-dimensional space of spatially organized receptor units whose function requires vectorial interactions.

Membrane microdomains

So long as spatial order of the fluid membrane is maintained, fluidity will actually increase the rate of coupling of independent molecules. It may be worth recalling here that the surface representation of antigen receptors on B and T cells would be very low, were such B and T cell receptors uniformly distributed over the entire cell surface, and that restriction of their distribution to selected domains of the lymphocyte surface might favor both their clustering by polymeric antigens and their recognition by membranous and cytosolic adaptor and transducer molecules. For instance, assuming it is a smooth sphere, a small B lymphocyte with a mean diameter of 8 μm would have a surface of about 200 μm^2 , but there must be at least equivalent (if not much higher) amount of surface membrane stored (e.g. for cell division) under the form of various membrane ruffles and pseudopodia or microprojections. Thus, assuming a near-maximal expression of 40 000 mIg molecules for at least 400 μm^2 B cell surface, one reaches the fairly low surface density of ≤ 100 mIg molecules per μm^2 . While this is a maximal estimate, it is interesting to consider that this corresponds to only one single mIg molecule per patch of 100 nm $\times$ 100 nm, which is about the size reported for some membrane microdomains! For comparison, the diameter of the membranous IgM stem (stalk) is in the range of 4 nm only, and the distance between its two Fv domains is about 12 nm. Because of such a low surface density of antigen receptors, cross-linking of two individual IgM molecules by an antigen would require much mobility, were they distributed at random.

Similarly, there would be a rather poor efficacy of coupling between recognition by the extracellular antigen/ligand-binding elements, and transduction

and signaling by the CD3 complex(-like) elements of the membranous receptor complexes, were they randomly distributed over the whole cell surface. Moreover, the antigen receptor complexes themselves should be in close proximity to their stoichiometrically associated, membrane-anchored and function-controlling elements such as specific protein kinases and protein phosphatases, as well as to the variety of CD coreceptors which are regulating the signal levels. Therefore, there is a high probability for such receptor-operator units to function within specialized membrane microdomains. The latter might not exist as such in the resting cells, and the fully functional signaling unit would probably proceed through *recruitment* of some key elements of the receptor-operator unit. Possibly, only a few of these units are functional at any given time, but a first successful coupling of recognitive elements with effector elements might cause something I would call 'membrane stressing'. This might be acting like a catalyst for further unit assembly, e.g. the activation of a phospholipase whose primordial membrane effects would be to favor the further segregation of the membrane into microdomains, which would much enhance the chances of encounters of relevant elements.

Proximity and promiscuity

Besides the *covalent* interactions of membrane elements such as the various polypeptide chains which constitute the TCR, BCR and MHC antigen receptors, and a number of oligomeric CD coreceptor components which are involved in coupling ligand adhesion to signal transduction, two major mechanisms may favor the selective encounters of membrane components: proximity and promiscuity. The differences between these two terms may look subtle or semantic, but they may be large in terms of mechanisms and consequences.

Promiscuity would refer to membrane components, both integral and peripheral ones, which are loosely held close to each other by *low affinity interactions* such as those taking place between elements of the 20 nm thick glycocalix (e.g. weak lectin-like interactions in a microenvironment where local carbohydrate concentrations may be in 0.1 M range) and those occurring between the array of membrane-stabilizing proteins constituting the endoskeleton. Moreover, promiscuity may also be created within the membrane by lipid domains showing hydrophobicity features which may be more or less favorable for the preferential localization of integral proteins with a TM anchor (TM proteins) or with a GPI anchor (GPI proteins), of cytosolic proteins with a

myristoyl anchor, and also more or less suitable for the association of some glycolipids, such as gangliosides, endowed with an innate tendency for self-association and microdomain formation with the membrane phospholipids. Molecular promiscuity may have a coordinated biosynthetic origin, most interacting elements being synthesized and organized as a membrane patch before the membrane vesicle reaches the cell surface.

Proximity would rather refer to a higher occurrence of membrane components within a microdomain, which would only be favored by the existence of *molecular boundaries* in the membrane, in the absence of specific molecular interactions, even of low affinity, between the components of the microdomain. Such domain boundaries might be constituted by protein fences both within the lipid bilayer (integral proteins) and on both of its faces by peripheral proteins, some of which constitute a subplasmalemmal skeleton (membranous endoskeleton) and some others participating to the cell glycocalix (membranous exoskeleton). Within such boundaries of the microdomain, the membrane components would thus be kept in close proximity to each other.

Specialized membrane microdomains defined by submembranous protein networks

In addition to those which may be defined by TM protein- or glycocalix-based fences and others which may depend on particular lipid clusters (caveolae), other membrane microdomains may be defined by the subplasmalemmal assembly of various types of protein skeletons. These endoskeletal networks may recruit a selection of peripheral and cytosolic proteins, with the eventual connection of a membrane patch to the actin microfilaments. At least four types of microdomains may be defined, the first one being mostly an endoskeleton, the next two involving TM proteins with intercellular adhesion sites, and the last one concerning microvilli and possibly ligand recognition.

In erythrocytes, a spectrin-based filamentous network is apposed to the inner face of the lipid bilayer, conferring mechanical support to the membrane. Several members of the *spectrin family* occur as endoskeletal components of nonerythroid cells (ankyrin, fodrin, TW260/240, dystrophin, dystrophin-related protein, α -actinin). These proteins constitute membrane skeletons with a fixed stoichiometry but a flexible morphology (due to the properties of spectrin). They help to organize and stabilize microdomains which are enriched in some

integral membrane proteins. None of these skeletal proteins is a TM protein, i.e. they cannot be directly in touch with the cell outside, but one of them (often ankyrin) can link the assembly to a TM protein (often a channel or transporter). Moreover, most of these proteins bind to actin, providing specific attachment sites for cytoskeletal components; the latter may thus define the topographical distribution and cell surface dynamics of such microdomains whose occurrence in leukocytes remains unknown.

Integrin-mediated adhesion to the extracellular matrix reveals the colocalization of two submembranous skeleton proteins, α -actinin and talin; these actin-binding proteins connect the cytosolic domains of integrins to a matrix of actin microfilaments and other actin-binding proteins, including vinculin, paxillin, tensin and zyxin. *Cadherin-mediated adhesion* similarly results in the localized recruitment to their cytosolic domain of several cytosolic proteins (β -catenin, plakoglobin, p120) which bind to α -catenin (homologous to vinculin), itself binding to fodrin and actin, with α -actinin joining the complex. In both the integrin and the cadherin cases, the networks of interacting submembranous skeletal proteins strengthen cell adhesion and provide protein scaffolds for signaling networks, which involve kinases, phosphatases, GTP-binding proteins and adaptor proteins.

Another actin-based cytoskeleton characterizes the noncontacting surface of epithelial cells, i.e. its apical surface which expresses numerous *microvilli*. Each microvillus is sustained by a bundle of actin filaments, cross-linked by villin and fimbrin, coupled laterally to the membrane by myosin I, and anchored into the cortical actin filament network by fodrin. In the case of epithelial/endothelial borders, the microvilli are found on the apical surfaces of the cells, thus facing the 'not self' in the lumen. Would adhesion through the integrin- and cadherin-based domains be rather involved in recognition of self, whereas microvillus-based recognition would be devoted to the not self? In the case of lymphoid cells, microvilli tend to redistribute to the area of contact with the target cell, possibly showing their direct involvement as an early recognition step. Assuming the analogy to epithelial cells goes further, lymphocyte microvilli might not mediate adhesion, but only be involved in signaling ligand recognition.

Another case for specialized membrane microdomains is found on the apical surface of epithelial cells: these are the *caveolae* which are 50–100 nm invaginations found at the bases of the apical microvilli. These membrane protein–lipid microdomains are remarkably resistant to detergent (e.g. Triton-X100)-mediated solubilization. They are

coated with caveolin, a TM protein which is a v-Src substrate, and they contain G protein-coupled receptors; in caveolae, caveolin exists as a heterooligomeric complex with integral proteins and known cytosolic signaling molecules, suggesting the involvement of caveolae in transmembrane signaling. Moreover, caveolae would recruit and 'cluster' GPI proteins (in a 'promiscuity' sense), such as the folate-binding protein (showing their important physiological role). In T cells, GPI proteins (e.g. Thy-1 or DAF[CD55]) may play a role in signal transduction, particularly through an activation of submembranous protein tyrosine kinases (e.g. Fyn or Lck), which are proteins anchored to the inner leaflet of the lipid bilayer by N-terminal myristoylation. It is assumed that the connection (as found by coimmunoprecipitation) of the latter proteins to the extracellular GPI proteins (whose anchor is restricted to the outer leaflet of the lipid bilayer) might be done by the TM protein caveolin.

Finally, the topography of the various microdomains might be determined on the cell surface by anchorage of the various scaffolds to the *microtubular cytoskeleton*. As suggested for the epithelial cell model, microtubule organization might confer a polarity to the lymphocyte for microdomain redistribution to the cap/uropod area.

Adhesion or recognition, but not both?

Does the cell segregate adhesion molecules and recognition-coupled effector molecules into separate microdomains? An *ad hoc* argument was made that molecules endowed with recognition of the non self, such as antigen receptors, might be naturally expressed on microvilli. Microvilli were indeed reported to express mIg at higher cell surface density than the rest of the B cell surface. Whether this is true for the TCR was not examined, but one may also assume that T cell microvilli might have the function of recognizing target cell-presented antigens. A microvillus redistribution to the intercellular contact area would also bring the caveolae to the same pole, if these two microdomains are topographically associated on lymphocytes, as they are on the apical surface of epithelial cells.

Since microvilli are labile structures which may grow or retract quickly, whereas caveolae may be structurally stable structures occurring (and possibly forming boundaries) at the microvillus bases, the high expansion and contraction of microvillus membrane might be explained if the fluid lipid bilayers would percolate between the caveolae: the lipids may rapidly flow through the caveolae network and go

back and forward between the bulk of the plasma membrane and the microvillus membrane domains. Selected membrane components, including proteins, would cross the caveolae network boundaries much more slowly.

Once recognition has occurred, microvilli could retract, bringing the lymphocyte closer to the other cell. At the membrane level, a fast microvillus retraction after ligand encounter might thus markedly increase the surface density of selected components of the 'recognition domain'. For instance, assuming a 1 μm long microvillus with a 0.1 μm diameter, its 0.16 μm^2 surface would be converted into a flat 0.008 μ^2 patch on the cell membrane, possibly causing a 20-fold increased density of selective TM proteins, GPI proteins and myristoylated proteins and other microvillus membrane components whose diffusion was delayed by the caveolae network. This mechanism would thus provide a higher occurrence for interactions of the receptor, adaptor and effector elements of the recognition units displayed on the former microvillus membrane, as well as higher chances of interactions of such initiating complexes with other effector components of the caveolae at the boundaries.

Clustering for cell activation, but capping against it?

How ligand binding results in a signal to differentiate or to divide is a complex sequence of events. Although the actual consequences of capping for the physiology of the cell remain poorly understood, it seems that clustering rather than capping actually initiates cell triggering. It is generally admitted that the very first signal is the clustering of receptors by interaction with a cross-linking ligand (e.g. polyvalent antigen, lectin, antibody). Capping itself may not be perceived by the cell as a triggering signal, although it may be used as a *scavenging* mechanism for the efficient removal of bound ligands and engaged cellular receptors. One could, however, speculate that a more efficient capping of antigen-mIg complexes on a B cell surface might lead to an earlier and/or more efficient endocytosis, processing and antigen presentation.

There is tremendous support for the generalization that clustering of plasma membrane components is a prerequisite for triggering. In all cases where a ligand is mitogenic, it is found to be bi- or polyvalent, and its monovalent derivatives are no longer mitogenic. Even more conclusive is the fact that monovalent, nonmitogenic ligands can be made mitogenic by polymerization. Thus, the cross-linking of membrane sites is required for triggering. Yet

attempts to establish a closer link between clustering and triggering are not easy, as the clustering of antigen receptors by itself does not appear to trigger the whole activation cycle. This first signal is obviously necessary but not sufficient to activate the cell.

Whether lymphocyte activation may involve more subtle and specific consequences of antigen receptor clustering, such as increased frequency of encounters between given elements of the B cell or T cell receptor complexes, is a matter for ongoing research. The essential fact is that mIg clustering, like patching of any other membrane component by its cognate ligand, creates patches of membrane with a *selective* component composition which might initiate cellular activation but which are normally removed by capping. Thus, capping rather appears as a mechanism which limits the *duration* of the signaling period. By limiting the persistence of patches of selected membrane components on the cell surface, capping may regulate cell activation by up- or down-modulating the overall signal delivered by clustered receptor units. The early changes in the physicochemical properties of the membrane normally last for a few minutes only, as does the normal persistence of the mIg clusters on the B cell surface (at least *in vitro*).

Too rapid a removal of clustered mIg by capping may actually impair triggering, this being due to insufficient first signal hits delivered to the cell, and thus resulting in a failure to reach a hypothetical threshold level for stimulation. Conversely, in the case of very delayed capping, the long persistence of large clusters of receptors would deliver excess signals which might lead either to cell paralysis and inactivation or to terminal differentiation, both of which pathways ultimately result in deletion of the cell concerned. Thus, the rate of capping-mediated removal of clustered receptors from a cell surface may be crucial to position the signal levels within a triggering window where cell activation to mitosis and clonal expansion will occur, a window defined by a minimum threshold level below which the signals are not perceived as activating and a maximum threshold above which the signals are inactivating the cell, potentially leading to 'clonal deletion'. The microdomain concept brings a novel dimension to the problem: in T cells, for instance, it may be crucial to know whether TCR/CD3-containing receptor-effector complexes, which if stimulated alone would lead to anergy, occur in the same or different microdomains as the CD28-operated units, whose involvement is needed for stimulation.

Abnormalities of capping

Various alterations of capping are found in cases of immunodeficiency and/or autoimmunity, or following cell treatment with pharmacological agents known to show immunomodulatory properties. Various agents or conditions, which may be physiological, pharmacological or genetic factors and are known to modulate the immune responsiveness, are also found to alter the rate of capping. Thus, capping of B cell mIg occurs at different rates for mice of different strains and shows different susceptibilities to pharmacological agents; immature, fetal or neonatal B cells cap faster than mature, adult B cells; peripheral blood lymphocytes from elderly human beings show decreased capping rates in comparison with young adults; and cyclosporine-treated B cells show a faster capping.

Within identical genetic contexts, single mutations, which do not seem to directly target components of the capping machinery, can affect the capping rate found for B cell mIg, such as the *xid*, *nu*, *lpr*, *gld* and *me^v* mutations. Presumably, such mutations lead to the selective development of some particular B cell subsets which may be minor components of the wild mouse B cell population. However, some mutations may directly touch the capped or associated components. Thus in the mouse, the *bg* mutation (a mouse model of the Chédiak–Higashi syndrome) targets a gene encoding a coiled-coil phosphoprotein 'Lyst' which may act on the microtubular network as a relay integrating cellular signal response coupling; the *Lyst* deficiency accelerates mIg capping and even allows capping of some lectins in the absence of treatments which weaken the microtubular restraints on membrane mobility. Similarly, the *sph* mutation (α -spectrin deficiency causing hereditary hemolytic anemia) accelerates the lectin or antibody-induced capping of membrane glycoproteins on erythroleukemia cells, suggesting that spectrin may limit the lateral mobility of integral membrane proteins in cells with a fluid membrane (i.e. other than the erythrocytes). Similarly, in human beings, several cases of abnormalities of leukocyte function and of capping and/or adhesion have been reported, such as in Duchenne muscular dystrophy (an abnormality of

dystrophin, a member of the spectrin family of membrane skeleton proteins) and in leukocyte adhesion deficiency (deficiency of the β_2 -integrins).

CARBOHYDRATE ANTIGENS

Cornelis PJ Glaudemans, Chief, Section on Carbohydrates, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland, USA

Copyright © 1998 Elsevier Ltd. All Rights Reserved.

Carbohydrates, containing n asymmetric carbon atoms, can exist in 2^n stereoisomeric forms. A common hexose possesses *a priori* four asymmetric carbon atoms (C-2, -3, -4 and -5) and thus can exist in 16 stereoisomeric forms (i.e. D-glucose, L-glucose, D-mannose, L-mannose, etc.). Each of these isomers can occur in either a six-membered (pyranose) or five-membered (furanose) ring form. When a hexose is in the ring form, the C-1 aldehyde function also becomes asymmetric, and the 1-hydroxyl group can assume either the α or the β configuration, thereby doubling the number of possible isomers. In total, a hexose can thus occur in an oligo- or polysaccharide in 64 different ways. This enormous capability for diversity makes carbohydrates very versatile as nature's alphabet for recognition in biological events, including immunology. Bacteria, viruses and mammalian cells nearly always have polysaccharides as capsular or cell wall material, and/or have glycolipids and glycoproteins on, or in, their walls, and these wall components or capsules often dictate the ensuing cascade of biological events in which they participate.

Structure of polysaccharides and the saccharides of glycoproteins and glycolipids

Polysaccharides, and the saccharide epitopes of glycoproteins and glycolipids, are secondary gene products. Thus, glycosyl transferases are encoded at the genetic level, and these in turn catalyze the formation of oligo- or polysaccharides or the glycosylation of proteins and lipids. One of the consequences for polysaccharides is that they have no uniform, sharply defined molecular weight but instead possess a molecular weight distribution. Linkages between monosaccharides in the polysaccharide chain are acetal linkages; they involve a carbon atom bearing two oxygen atoms: the ring oxygen and the intersaccharidic oxygen. Acetals are susceptible to acid-catalyzed hydrolytic cleavage, as well as enzymic cleavage, since both operate by the same chemistry.

Sugar residues in an oligo- or polysaccharide chain frequently carry substituents such as (acyl)amino-, carboxyl-, acetoxyl, pyruvoyl-, phosphorylcholine-, or can be esterified with long-chain fatty acids. This additional diversification can profoundly affect the

immunogenicity or biological activity of the entire molecule.

Naturally occurring carbohydrate antigens can be divided into two main categories, which can again be subdivided:

1. Polysaccharides
 - Bacterial, capsular polysaccharides
 - Bacterial cell wall polysaccharides
 - Bacterial lipopolysaccharides
 - Plant polysaccharides (e.g. cellulose, etc.)
 - Storage polysaccharides (e.g. glycogen, etc.).
 - The last two classes of polysaccharides will not be discussed here.
2. Carbohydrates borne on other (macro)molecules
 - Glycoproteins
 - Glycolipids.

Concerning (1), capsular polysaccharides of bacteria exist on the outside of the cell wall. The loss of capsular material does not lead to autolysis, but it does often lead to loss of virulence. By and large, bacterial capsular polysaccharides are made up of small, linear or branched units (of from one to several sugar residues). These are repeated with great regularity to make up the extended, polymeric chain. Most of these polysaccharides possessed by bacteria within a given species (e.g. within the gram-positive species *Streptococcus pneumoniae* there are more than 80 types) show pronounced immunologic specificity. However, if capsular polysaccharides share certain features between them that are structurally akin, they may cross-react with each other's immune sera. If the structural similarity is extensive, infection with one could even confer cross-reactive protection towards the other. For instance, the capsular polysaccharide from *S. pneumoniae* type III is a high molecular weight, linear heteroglycan (= a polysaccharide containing differing sugars) made up of D-glucuronic acid (in the six-membered ring, or pyranose form: Glc₆A) whose acetal carbon-1 is linked to the 4-hydroxyl group of D-glucose (also in the pyranose form) by a β linkage, and these disaccharide units are repeated by being linked to each other by $\beta(1\rightarrow3)$ linkages to make up the extended polymeric chain (I).

I

The high molecular weight capsular polysaccharide from *S. pneumoniae* type VIII has a tetrasaccharide repeating unit, the disaccharide part of which is identical to the one above. In addition it has a 4-linked glucose that is linked $\alpha(1\rightarrow4)$ to a galactose residue. The tetrasaccharide repeating units are connected by $\alpha(1\rightarrow4)$ linkages (II).

II

These two polysaccharide antigens – having 50% of their structure in common – show extensive cross-reaction with one another's serum antibodies.

Several gram-negative bacteria can produce extracellular polysaccharides. When these surround the organism, i.e. when they become a capsular polysaccharide, they also dictate the immunologic specificity of the organism. Those polysaccharides are often acidic. They can have intracatenary phosphoric diester groups, substituents such as pyruvic acid acetalated with certain sugar residues, or they can carry simple uronic acids. An example is the capsular antigen of *Escherichia coli* K100, possessing intracatenary diester groups (III).

(where Rib_r stands for ribofuranosyl).

III

Differing species can show cross-reactivity as well, and these can be biologically significant. For instance the antigen of *Hemophilus influenzae* type b (Hib) shows near structural identity (IV) with the capsule of *E. coli* K100 (see above) and protective antibodies towards Hib are believed to result from the presence of that *E. coli*.

H. influenzae type b (Hib)

IV

Cryptococcus neoformans is the only fungal species of unarguable pathogenicity that possesses capsular polysaccharides, whose most abundant components are glucurono-xylo-mannans. There also, the capsule may be a factor in virulence. Returning to bacteria: compromise of the underlying bacterial cell wall, for instance through interference of the biosynthesis of the wall's peptidoglycan (see below)

by penicillin, causes autolysis, as the wall's integrity arises mostly from a high molecular weight, cross-linked and 'net-like' peptidoglycan polymer. That substance is composed of two components. The first is a polysaccharide of alternating *N*-acetyl-D-glucosamine (D-GlcNAc), linked $\beta(1\rightarrow4)$ to *N*-acetyl muramic acid (NAM = D-GlcNAc carrying a lactic acid substituent at its O-3). The carboxyl group of the lactic acid in NAM is attached to a short peptide chain, which, in *Staphylococcus aureus* consists of L-alanine, D- γ -glutamic acid, L-lysine and D-alanine. The D-alanine's carboxyl end is connected by a pentaglycine to the ϵ -amino group of the lysine of another tetrapeptide. Further bridging is probably achieved to make this giant molecule three dimensional. The peptides vary in differing bacterial species, but the intricate, resulting network of cross-linked polysaccharide/polypeptide is very similar (V).

Teichoic acids, composed of sugar residues, some of which are linked by phosphodiester- rather than acetal-linkages, may be attached to some of the GlcNAc residues by a phosphate linkage. Peptidoglycans occur in both gram-positive and gram-negative organisms, where they have similar, albeit not identical, structures.

Gram-negative bacteria possess a lipopolysaccharide (LPS), also called endotoxin. It is made up of three distinct segments.

First, the *lipid A*, which consists in most cases of two residues of *N*-acyl D-glucosamine, linked $\beta(1\rightarrow6)$. This disaccharide fragment is phosphorylated at positions 1 and 4', and each residue is extensively esterified, as well as *N*-acylated, with long-chain fatty acids. The lethal toxicity the LPS can exhibit in animals (and humans) resides in the lipid A segment.

Second, the so-called *core region* is covalently attached to the 6' position of lipid A. It is a fairly short oligosaccharidic segment (usually less than 15 sugars) consisting of one or more residues of keto-deoxy-octulosonic acid (forming the linkage with the lipid A), heptoses, various sugars, ethanolamine (EtAm) and phosphate (P) substituents. It is similarly but not identically structured in most Gram-negative bacteria.

Third, the so called *O-polysaccharide* (O-PS) can possess up to roughly 100 sugar residues, made up of distinct repeating units, linear or branched, that can involve (from one to) several sugars. It is covalently linked to the core region.

The lipid A segment is inserted – and anchored through the hydrophobic interaction of its fatty acid chains with the cell wall lipids – into the fluid lipid bilayer of the bacterium's wall. The entire LPS is oriented so that its O-polysaccharide projects out

from the bacterial wall into the surroundings. Consequently, the O-polysaccharide often dictates the immunodeterminant behaviour of the organism, and it differs for each type within a species. Most wild-type bacteria carry O-polysaccharide and are then said to be in the smooth- or S-form. Bacteria not carrying O-polysaccharide, but only possessing the lipid A/core combination are said to be of the rough- or R-form. These terms are descriptive of their respective colony morphology. The presence of O-polysaccharide cannot be regarded as a necessary factor for pathogenicity, since R-type LPS is observed in some wild-type bacteria that are highly pathogenic in humans (e.g. *Bordetella pertussis*, *Neisseria gonorrhoeae*, and others). Below are two examples of an LPS. The first is for *Salmonella*, the second for *Legionella pneumophila*. Note that although the core regions are quite different, both are short saccharidic stretches situated between the lipid A and the O-chain. Note also that KDO is the sugar residue linked to the lipid A portion (VI):

where GlcNAc = N-acetyl D-glucosamine, Gal = galactose, Hep = Heptose, KDO = keto-deoxy-octulosonic acid, EtAm = 2-aminoethyl, P = phosphate, FE = fatty acid ester. The lipid A is indicated on the right, while the O-polysaccharide is indicated on the left. The location of the phosphates or 2-amino-phosphates, or the branch-terminating KDO, remains tentative (VII).

In the case of systemic infection by gram-negative organisms, the overwhelming amount of solubilized endotoxin produced by bacterial lysis can cause shock and even death. It is interesting to note that affinity-purified rabbit anti-LPS immunoglobulin M (IgM) and IgG protects rats lethally challenged with *Pseudomonas aeruginosa*.

Concerning (2), in addition to the polysaccharide antigens, such as discussed above, many mammalian or viral cell walls carry glycoproteins and/or glycolipids on or in them, and these can define their antigenicity. Glycoproteins are proteins that are naturally substituted by short and/or medium length

VII

oligosaccharide substituents, whose internal linkages are purely of the acetal type. The linkage between protein and carbohydrate can be of the O-linkage type (C-1 of the sugar is glycosidically linked to the hydroxyl of a serine or threonine residue, thus forming a regular glycosidic linkage), or of the N-linkage type (C-1 of the sugar is linked to the NH_2 of an asparagine residue of the protein, forming an N-glycosidic linkage). Two examples are given below, one is human gastric mucin and the other is one of the many glycoforms of an oligosaccharide chain that occurs on human IgG at asparagine (Asn)-297 of the heavy chain of the immunoglobulin (Ga1NAc stands for N-acetyl galactosamine) as in VIII.

The term 'neoglycoprotein' indicates a glycoprotein that arises through synthetic glycosylation of a protein. Several 'conjugate' vaccines are in fact neoglycoproteins where the saccharide part is the desired immunodeterminant that is linked synthetically to a carrier protein.

Glycolipids consist of an oligosaccharidic fragment linked to, for instance, ceramide. They are frequently of fairly low molecular weight, and the carbohydrate moiety is the immunodeterminant. Below is shown a typical glycolipid (GM1 ganglioside) where NeuAcid stands for neuraminic (= sialic) acid (IX).

Hakmori and associates have shown that glycolipids can seat their lipid moiety in cell wall membranes, projecting their carbohydrate antigenic grouping into

the environment outside the cell. Human blood-group specificity is a function of oligosaccharidic determinants carried on erythrocyte surfaces as glycolipids or glycoproteins. Transfusion into individuals possessing differing blood groups causes an antibody response in the host due to the immunogenicity of the carbohydrate determinant, or causes the transfused antigen to cross-react with pre-existing antibodies already present in the host. Both of these substances, glycoproteins and glycolipids, can occur as oncodevelopmental antigens. These are antigens which appear and disappear during successive stages of embryogenesis. They may reappear in adult life as tumor antigens, but are not necessarily unique to cancer cells *per se*, as they can occur at low levels in most normal adult cells.

Viruses, including the human immunodeficiency virus (HIV), are usually not capable of encoding for glycosylation enzymes. This means that the glycoprotein-120 on the surface of the HIV virus has its carbohydrates (making up some 50% of the gp120) attached by enzymes and substrates defined by the cells the virus has infected. The various glycosyl transferases or substrates may be modified by the infection, and thus the expressed virus can possess differing glycan structures. The diversity amongst N-glycans in gp120 is very great – there is more diversity than there are glycosylation sites – indicating structural heterogeneity. Since the glycans are attached by the mechanism of the host cell, they may

VIII

IX

present an image of 'self' to the host, and thus escape immune surveillance. Nevertheless, some monoclonal antibodies showing specificity for rare carbohydrate structures can neutralize a broad range of HIV-1 and -2 isolates, as well as block syncytia, even by virus taken directly from patients with the acquired immune deficiency syndrome (AIDS).

Conformation in solution

Polysaccharides as well as the oligosaccharide components of glycoproteins and glycopeptides and glycolipids may be linear or branched, homo- or heteropolymer, neutral or charged. These oligo- and polysaccharides can assume tertiary (globular) structure, and in some cases the particular spacial presentation of a carbohydrate becomes critical in dictating the immunologic specificity. For instance, Jennings and associates have evidence that the capsular polysaccharide of group B streptococcus assumes a conformation in which short, sialic acid-terminated side-chains each form a hydrogen bond with an intrachain GlcNAc nearby. That results in an immunologically specific conformation. This, even though the sialic acid itself is not a (contact) immunodeterminant, and apparently only functions as the vector in creating the correct conformational rigidity. However, it must be kept in mind that for carbohydrates, conformational changes on the polymeric level are easier to achieve (i.e. have lower energy barriers) than they are for proteins. Indeed, various conformational possibilities are probably populated in proportion to the energy differences between them. Critically important requirements such as in the example above do not (yet?) appear ubiquitous for carbohydrate antigens. It should be realized that, for proteins, loss of tertiary structure (i.e. denaturation), once it occurs, is often hard to reverse, even when conditions are changed, while denaturation of polysaccharides is unknown, or rare at best. Polysaccharides are quite heat stable – although autohydrolysis can occur if they are acidic polysaccharides – and their solution structure is less influenced by changes in electrolyte concentration unless they carry charged groupings.

Immune response to carbohydrates

The early discovery that the 'soluble-specific substance', the capsular material of *Streptococcus pneumoniae*, is immunogenic in humans prompted immunizations with purified polysaccharide in the early 1940s. The contemporary and subsequent great success of the treatment of pneumonia with antibiotics rapidly diminished the initial interest in vaccines. However, the continued frequency of serious diseases such as pneumococcal meningitis, and the appearance of bacterial strains showing resistance to antibiotics, including *S. pneumoniae*, has rekindled an intense interest in immunization with polysaccharide-based vaccines. Unfortunately, polysaccharides themselves are often poor immunogens, particularly in infants and in immunocompromised individuals. In addition, for pneumococci, the existence of 84 distinct serotypes has complicated the issue. For this organism, penicillin resistance is concentrated amongst the (pediatric) serotypes 6, 14, 15, 19 and 23, while types 1, 2, 3 and 4 are still largely penicillin sensitive at this time. Polysaccharides are conveniently termed 'T cell independent' (TI) immunogens, and they do not induce immunologic memory, which is required for booster responses. Often only a limited number of B cell clones are activated, resulting in restricted – albeit polyclonal – heterogeneity. Most polysaccharides can induce a state of unresponsiveness, or tolerance, and also do not elicit delayed-type hypersensitivity. In addition, the immunogenicity of polysaccharides increases with molecular weight, and when that is less than 50 kDa the polysaccharide is nonimmunogenic. For all these reasons, immunization with purified polysaccharides has been only partially successful. Frequently, covalent linkage of the carbohydrate determinant epitope, or the entire polysaccharide, to a protein carrier to give a so-called 'conjugate vaccine' allows enhancement of immunogenicity in animals and humans, and instates immunologic memory. The resulting antibodies are protective, and show binding to the parent capsular polysaccharide from which they were derived. Some such immunogens, i.e. Hib polysaccharide linked to tetanus toxoid, have been licensed as human vaccines, and have become very successful in

the immunization of infants. The length of an oligosaccharide, to be attached to proteins to form a suitable conjugate vaccine, must vary. In cases where there is a distinct tertiary structure (see above) of the saccharidic immunodeterminant in the natural, bacterial or viral product, that tertiary structure must undoubtedly be mimicked by the (synthetic or derived) saccharide to be conjugated. The resulting antibodies generated by the immune response would then be able to recognize readily the natural immunogen.

Interaction of carbohydrate antigens with antibodies

In the 1960s Kabat showed that polyclonal anti-dextran antibodies bound maximally to about five sequentially linked sugar residues of the antigen. Modern work on monoclonal antibodies and sharply defined carbohydrate immunodeterminants have since shown that the determinant in an antigenic polysaccharide can be 2–4 sugars long. Affinity constants for the entire immunodeterminant can range from 10^3 to 10^6 M^{-1} . These values suffice for the initiation of an immune response. Antibodies elicited by polysaccharides can be directed against either the interior segments or the terminal segment of the antigenic chain, and the antibody can bind the polysaccharide chain on its surface, or inside cavities. In the case of a monoclonal antibody to $\alpha(1\rightarrow6)$ -dextran it was shown that one group of monoclonal antibodies could bind the dextran all along its chain. Another set of monoclonal antibodies could bind only to a stretch of residues of the dextran that had to include the single chain-end glucose residue of the dextran. The latter was held inside a pronounced cavity, while its three sequential sugars were held near the surface of the immunoglobulin. It was found that an antibody combining area was thus made up of a set of subsites, and these could be mapped. Each one could

accommodate a single sugar residue of the polysaccharide. All together these subsites can bind the entire immunodeterminant of four sugar residues. Generally, the major subsite shows an affinity of 10^2 – 10^3 M^{-1} for its single carbohydrate residue, while the other subsites often possess far less affinity for their particular sugar residues. In the case of a comprehensively studied monoclonal antibody to a homopolysaccharide (galactan), it was found that the immunoglobulin could also maximally bind four sugar residues. Here the monoclonal immunoglobulin could access and bind these repetitively occurring four galactosyl residues in the interior of the polysaccharide chain. All four subsites of the immunoglobulin were on the protein surface, and the subsite with the major affinity was located *within* the sequence of four. In yet another study, a monoclonal anti-*Shigella dysenteriae* type 1 antibody could also bind interiorly located repeating determinants of the bacterium's O-specific heteropolysaccharide.

CARBOHYDRATES, IMMUNE STIMULATING

Ian R Tizard and Yawei Ni, Department of Veterinary Pathology, The Texas Veterinary Medical Center, Texas A&M University, and Carrington Laboratories Inc., Texas, USA

Recent developments in glycobiology have shown that carbohydrates play an important part in diverse immunological processes such as opsonization and phagocytosis of microorganisms, and cell activation and differentiation (Table 1). Carbohydrates exert

their functions through interacting with carbohydrate-binding proteins or lectins which are widely distributed in mammalian tissues including those of the immune system. Those with immune-stimulating effects are usually large polymers of glucose (glucans

Table 1 Immunostimulating carbohydrates and their structures

Carbohydrates	Structures
β -Glucans	$\beta 1 \rightarrow 3$ Glucose
Lentinan	$\beta 1 \rightarrow 3$ Glucose with $\beta 1,6$ -glucose branches
Mannan (plant)	$\beta 1 \rightarrow 4$ Mannose
Mannan (yeast)	$\alpha 2 \rightarrow 6$ Mannose with $\alpha 1,3$ -mannose branches
Acemannan	$\beta 1 \rightarrow 4$ Acetylated mannose
Pectin	Mainly polygalactose
Inulin	$\beta 2 \rightarrow 1$ Fructofuranosyl- α -glucose
Levan	$\beta 2 \rightarrow 6$ Fructose
Xylan	$\beta 1 \rightarrow 4$ Xylose
Lichenan	$\beta 1 \rightarrow 4$ and $\beta 1 \rightarrow 3$ Glucose

and lentinans), mannose (mannans), xylose (hemicelluloses), fructose (levans) or mixtures of these sugars.

Immune stimulation

Complex carbohydrates act as immune stimulators through two distinct mechanisms. Some, such as the fungal glycans, activate macrophages while others, such as lentinan, are T cell stimulators. Other carbohydrates, such as acemannan, derived from the pulp of the *Aloe vera* plant, act on both macrophages and T cells, and as a result, may influence both cellular and humoral immunity.

Intravenous injection of purified glucan in rodents results in an increase in liver and spleen weight attributed to increased macrophage activity. Clearance of colloidal carbon is significantly enhanced in glucan-treated animals. Macrophages from glucan-treated mice are larger than controls and attach and spread more rapidly on glass. These same macrophages show augmentation of their chemotactic activity. Spleen cells from glucan-treated mice elicit a much more severe graft-versus-host reaction in recipient animals than do cells from normal mice. Administration of glucan to irradiated mice prior to bone marrow transplantation has no effect on syngeneic bone marrow grafts but may prevent acceptance of allogeneic or xenogeneic bone marrow. Depending on the injection protocol, glucan administration to mice may either enhance or depress the *in vitro* response of isolated spleen lymphocytes to concanavalin A and *Escherichia coli* endotoxin.

Lentinan has an adjuvant effect on the response of mice to sheep red cells having a greater effect on the immunoglobulin G (IgG) response than on the IgM response and it enhances antibody-dependent cellular cytotoxicity (ADCC) reactions. Inulin, a poly-

saccharide consisting of fructose and glucose, also has adjuvant properties. It increases the mouse IgG response to keyhole limpet hemocyanin as well as delayed-type hypersensitivity (DTH) reactions to sheep red blood cells. Levan causes macrophage spreading and swelling and stimulates their acid phosphatase and peroxidase activities. β -Glucan and inulin exist in insoluble or microparticulate forms. The microparticulate carbohydrates are better adjuvants because of enhancement of antigen phagocytosis. Targeting antigens into the phagocytic pathway is required for inducing a strong cell-mediated response, a key element for viral and tumor vaccines.

Interaction with lectins on immune cells and the consequent changes in cellular functions is most likely an important underlying mechanism for the observed immunostimulation and adjuvant effect of these polysaccharides. Macrophages play a central role in initiating the immune response. There are several different lectins on macrophages, including the mannose receptor. The receptor on macrophages for β -glucan is Mac-1 (CD11b/CD18).

Antimicrobial effects

Because glucans activate macrophages and stimulate their lysosomal and phagocytic activity, they stimulate immunity to bacterial diseases. Thus, glucan has a protective effect against experimental footpad inoculation of *Mycobacterium leprae*. It reduces the concentration of both viable and dead bacilli in the lesion. Mannan, in contrast, has only a brief protective effect while lentinan is inactive in this system. Intraperitoneal glucan therapy also enhances survival in mice challenged intraperitoneally with virulent *E. coli*. This is probably due to enhanced macrophage phagocytosis and accelerated blood clearance of bacteria.

Attachment to cell or tissue surfaces is often the first step in microbial invasion. This process is mediated by adhesins on the surface of bacteria, many of which are lectins. Thus, blockage of the interaction between bacterial lectin-like adhesins and cell surface oligosaccharides can be a mechanism for the antimicrobial effect of these polysaccharides. That is, these polysaccharides act as structural analogs of the cell surface carbohydrate receptors, binding to bacterial adhesins and therefore preventing them from attaching to cell surfaces. Sugars or oligosaccharides that are known to interact with lectin-like adhesins of a specific bacteria have been shown to inhibit its infection in animal models.

Effects on tumors

The practical importance of complex carbohydrate therapy may rest on their use as immune stimulants in humans or animals suffering from neoplastic conditions.

Glucans

Although common polysaccharides such as starch ($\alpha 1 \rightarrow 6$ glucan), and inulin (fructan) do not have antitumor activity, there is abundant evidence that some mannans and glucans are very potent anticancer agents. The factors that determine this are unclear. The soluble D-glucans have antitumor activity if they are mainly linear, without excessively long branches, and provided they are relatively resistant to degradation by glucanases. Thus glycogen, starch and dextrans are inactive while compounds with long stretches of $\beta 1 \rightarrow 3$ linkages are effective. Dextrans may be made active if derivatized with diethylaminoethyl groups. Studies on synthetic, $\beta 1 \rightarrow 6$ linked celluloses suggest that antitumor activity against sarcoma-180 in mice is greatest in molecules with a high degree of polymerization and homogeneous distribution of side-chains.

Intravenous glucan inhibits the growth of a murine allogenic adenocarcinoma and increases tumor macrophage populations. The glucan decreases the number of hepatic metastases as well as the size of the primary tumor. Enhanced Kupffer cell antitumor activity is correlated with this increased resistance to hepatic metastases. Intravenous administration of soluble glucans also results in a significant reduction in the growth of syngeneic murine mammary carcinoma and melanoma B16. Glucan from *Saccharomyces cerevisiae* has been reported to reduce the size of malignant melanomas and adenocarcinomas in patients with advanced neoplastic disease when administered in and around selected lesions. This reduction in size is associated with necrosis, abscessation and liquefaction of the tumor and a monocytic infiltrate. Water-soluble glucan administered in combination with lymphokine-activated killer (LAK) cells to mice, significantly suppresses the growth and metastasis of a reticulum cell sarcoma. This therapy increased splenic natural killer (NK) cell activity as well as Kupffer cell tumoricidal activity.

Other investigators have failed to substantiate the antitumor activity of glucans in syngeneic systems. Thus when *Saccharomyces* glucan was tested in a guinea pig hepatoma, two murine fibrosarcomas, a murine melanoma and a murine adenocarcinoma and compared with BCG vaccine, no effect was noted. Intralesional, intraperitoneal or intravenous administration of glucan was also found to be inef-

fective in the murine system. The glucan had no significant effect on tumor size, tumor incidence or host survival. It was concluded that the effects of glucan, although impressive in allogeneic systems (such as the sarcoma-180 system), are much less effective in syngeneic tumor systems.

Saccharomyces glucan probably exerts its anti-tumor effects by activating macrophages. Its activity appears not to be T cell mediated since administration of glucan severely inhibits the growth of melanoma B16 cells in nude mice. This antitumor activity in nude mice was associated with enhanced macrophage phagocytosis. The glucan probably stimulates macrophages to produce cytokines such as interleukin 1 and tumor necrosis factors. Thus macrophages from glucan-treated animals have been shown to release factors cytotoxic for tumor cells. Glucan also increases serum lysozyme levels, suggesting increased macrophage function and stimulated *in vivo* and *in vitro* secretion of interleukin 1 (IL-1). IL-2 production by splenic lymphocytes is enhanced 6 h after glucan administration and remains elevated for 9 days, presumably in response to the IL-1. Peak plasma IL-1 and IL-2 activities are found 9 and 12 days, respectively, following glucan administration. Given the very short half-life of these interleukins, this sustained elevation of IL-1 and IL-2 suggests that there is a very high rate of production.

Lentinans

Lentinan is a glucan derived from *Lentinus edodes*, a common edible mushroom. It has been shown to be active against several different allogeneic and syngeneic tumors. Lentinan, like other glucans has no direct cytotoxicity on tumor cells. Nevertheless it shows an optimal dose for antitumor action. The antitumor activity of lentinan varies between mouse strains which may be classified as either high or low responders. In strong responder mice, lentinan will completely regress 3-methylcholanthrene-induced transplantable fibrosarcomas. Lentinan is very effective against mouse methylcholanthrene-induced primary tumors in combination with cyclophosphamide. When administered to cancer patients in phase I and II trials, encouraging results have been obtained.

The antitumor activity of lentinan, unlike that of glucan, does not occur in neonatally thymectomized mice or in mice treated with antilymphocytic serum or by whole-body irradiation. It does not increase phagocytosis but it can stimulate macrophage cytotoxic activity *in vivo*. As a result, the antitumor effect of lentinan may be blocked by antimacrophage agents such as carrageenan or silica. Lentinan does not accelerate antibody formation, nor does it cause

an increase in blood lymphocytes, accelerate allograft rejection or influence delayed-hypersensitivity reactions.

Mannans

Mannans with significant antitumor activity have been isolated from several species of yeast. They have been tested for activity against sarcoma-180 in Swiss albino mice. There appears to be no relationship between the amount of glucose in these mannans and their activity. The mannan from *C. utilis* that contains an α -linked glucose is poorly inhibitory while the mannan from *C. albicans* that contains a β -glucan component is highly active. Mannans from *S. cerevisiae* and from *Candida utilis* inhibit the growth, not only of sarcoma-180 but also of 3-methylcholanthrene-induced tumors, Ehrlich carcinoma and NF sarcoma. None of these mannans appear to be active against the ascites form of sarcoma-180.

When mannoglucan prepared from *Magnaporthe grisea* is administered intravenously to C3H mice bearing the solid MH134 hepatoma, the blood flow to the tumor is inhibited within 6 h and tumor growth retarded within 3 days. If the tumor mass is excised and extracted at various intervals after administration of mannan, a soluble cytotoxic factor is detectable in the tumor homogenate. This factor is probably a form of tumor necrosis factor (TNF) since its activity is inhibited by anti-TNF serum, it has the same molecular weight range as TNF (70–80 kDa) and the dose dependencies of the cytotoxin and TNF are similar.

Acemannan (polyacetylated mannan) obtained from *Aloe vera* stimulated a tenfold release of ^{51}Cr from labeled tumor cells in the presence of macrophages. When injected intraperitoneally into female CFW mice subcutaneously implanted with murine sarcoma cells, acemannan reduces mortality from 100% of the control animals to 60–65% mortality in treated animals. Acemannan-treated animals exhibit characteristics of *in vivo* tumor necrosis, including development of concave liquefied areas on the tumor mass, and show visible evidence of necrotic toxemia. Necrotic tumors are found to exhibit central necrotic foci with hemorrhage and peripheral fibrosis. Similar effects have been observed in cats and dogs with spontaneous fibrosarcomas treated with acemannan.

Levans

The antitumor activity of levans, unlike that of the other polysaccharides described above, is a result of its ability to stimulate not only macrophages, but also B cells and T cells. For example, levan is a B

cell mitogen and can therefore stimulate a polyclonal B cell response. Inhibition of growth of Lewis lung carcinoma (3LL) by levan in mice is probably due primarily to macrophage activation. The site and timing of treatment with high molecular weight levan (2×10^4 kDa) significantly affects its activity against transplanted AKR lymphoma. Thus tumor growth is best inhibited by inoculation of levan directly into the primary tumor soon after tumor inoculation. It is ineffective if administered more than 2 days later. However, metastases are most effectively inhibited by intraperitoneal inoculation, suggesting that macrophage activation may be required for antitumor activity.

Pectin

Pectin, a galactose-rich carbohydrate abundant in citrus, is also known to have an antitumor effect. Inhibition by pectin of the metastasis of prostate cancer cells has been shown in a rat model. It has been suggested that pectin blocks galectin-3, a galactose-specific lectin, on cancer cells so that they cannot interact with the cellular matrix and therefore cannot emigrate.

In conclusion, it is clear that many complex carbohydrates have immunostimulating activity which may be of use for the treatment of malignancies. However, all complex carbohydrates clearly do not have the same mode of action, but act on different components of the immune system. Further studies are clearly required to determine the optimal conditions for their use in humans and animals. Recent developments in understanding carbohydrate–lectin interactions in the mammalian system will certainly add to these efforts.

CARDIAC DISEASE, AUTOIMMUNE

John B Zabriskie, The Rockefeller University, New York, USA

Allan Gibofsky, The Hospital for Special Surgery, New York, USA

In contrast to the extensive experimental and clinical knowledge that has accumulated concerning immunological and autoimmune mechanisms in the pathogenesis of tissue injury and dysfunction, notably the kidney, the concept that autoimmunity might play an important role in cardiac disease is just beginning to emerge. The slow progress in this area is, in part, due to the lack of good experimental models of autoimmune heart disease and also perhaps because of the difficulty of direct accessibility to the target organ itself. With the advent of the endocardial biopsy and other technological advances in cardiology, the ability to study cardiac tissue '*in situ*' has improved considerably and should provide the investigator with reasonable amounts of material for study similar to that seen since the advent of the renal biopsy.

These drawbacks notwithstanding, knowledge supporting the idea of autoimmune mechanisms in human heart disease has evolved greatly over the last two decades.

Microbe-induced cardiac autoimmunity

Rheumatic fever

The 'grand-daddy' of all microbial-induced autoimmune heart disease is rheumatic fever (RF). The concept of autoimmunity playing a role in this disease was introduced over 50 years ago by a number of investigators when antibodies to heart were noted in the sera of patients with acute rheumatic fever (ARF) and/or rheumatic heart disease (RHD). The origin of these antibodies was better defined when Kaplan and colleagues noted that immunization of rabbits with group A streptococci induced antibodies that bound to human heart in a manner strikingly similar to that observed with human patient sera. Further experiments revealed that the cross-reacting

antigen being identified was similar to (but not identical with) M protein and was also present in a limited number of group A streptococcal strains. Fischetti and colleagues identified the complete chemical structure of the M protein and demonstrated a close homology of the M protein moiety with cardiac cytoskeletal proteins. Further studies by Sargent and coworkers have clearly demonstrated that the M protein moiety contains numerous epitopes cross-reactive with certain cardiac proteins (e.g. tropomyosin and myosin) including those unrelated to the cytoskeletal proteins.

Similar studies in our own laboratory demonstrated the presence of a second cross-reactive antigen residing in the streptococcal membrane unrelated to M protein. This antigen was present in all streptococcal throat stains tested, and has been purified to a series of four peptides ranging in molecular weight from 23 to 22 kDa. An important feature of this protein was the demonstration by van de Rijn that the heart-reactive staining pattern of ARF sera was completely abolished by preabsorption of the sera with these closely spaced peptides. Further studies on lymphocytes by Zabriskie from ARF patients revealed enhanced cellular reactivity to this membrane antigen but not the cell wall antigen. This reactivity was confined to membrane preparations from streptococcal throat strains and not strains isolated from skin-associated streptococcal infections.

Autoimmune mechanisms are also thought to play a role in another major clinical manifestation of ARF, namely rheumatic chorea. Through the work of Husby and Williams, it was clear that the sera of patients with active chorea contained an antibody which bound to the cytoplasm of the cells of the caudate nuclei and was specific for these cells. The presence of the antibody correlated with the clinical activity of the disease and could be absorbed by streptococcal antigens. Further, the antibody was

detected in the cerebrospinal fluid of five patients with active chorea.

The nature and reactivity of lymphocytes from the RF valvular lesions is an area of active investigation in our laboratory. For example, using a panel of monoclonal antibodies specific for various cell surface markers, Dr Kemeny demonstrated that valvular lesions contained equal numbers of macrophages and T cells. Helper T cells predominated in the more active cardiac lesions; the T helper/T suppressor ratio in chronic carditis closely resembled that seen in normal peripheral blood. Recently, Dr Yoshinaga extended these experiments one step further and was able to isolate and clone T cell lines from these valvular specimens. When these T cell clones were stimulated with various streptococcal antigens, only streptococcal membrane antigens isolated from rheumatic fever-associated strains elicited a reaction in proliferation assays. Antigens isolated from nephritogenic strains or antigens from other groups of streptococci were nonreactive. One unanticipated and therefore surprising finding was that none of these T cell clones reacted against cardiac antigens or a variety of purified M protein antigens. In contrast to these findings Guilherme and colleagues have isolated individual T cell clones from RF valvular specimens which reacted both with streptococcal antigens and mammalian cytoskeletal proteins. The exact nature of these reactive antigens is under investigation.

The question of whether or not these heart-reactive antibodies or activated T cells isolated from patients are actually cytotoxic for the relevant tissue antigens has been difficult to prove. The experiments of Yang and colleagues clearly demonstrated that guinea pigs sensitized to streptococcal membranes produced activated T cells specifically cytotoxic for guinea pig neonatal myofibers but not for other tissues, whereas immunization with cell walls did not. However, the addition of heart-reactive antibodies obtained from the sera of these animals did not enhance the cytotoxicity, indicating that the observed cytotoxicity was antibody independent. The few experiments performed to date with cells obtained from 'inactive' rheumatic fever patients also show increased cytotoxicity for human atrial myofibers. Once again, the addition of heart-reactive antibody from the sera of these patients did not enhance the cytotoxicity. These results would suggest that cellular autoreactivity by activated T cells may play a more important role in the rheumatic cardiac lesion than previously thought.

In this context, recent observations by Cunningham and her coworkers are worth mentioning and may correlate with observations made by Rose and colleagues in an experimental model of cardio-

myopathy (see below). Using streptococcal-induced monoclonal antibodies that cross-react with M protein and human cardiac myosin, they could neutralize coxsackieviruses B3 and B4. The viral-neutralizing antibodies were also cytotoxic for heart and fibroblast cell lines and reacted with viral capsid proteins on western blots.

Given the evidence of an abnormal host immune response to streptococcal antigens cross-reactive with relevant target antigens, the tantalizing and as yet unresolved question is whether there is a genetic basis for this response in rheumatic fever patients. Beginning with Cheadle's work 100 years ago, numerous investigators have presented evidence for and against this concept. Recent articles have suggested that susceptibility to ARF following streptococcal infection might be related to alleles of the human major histocompatibility complex (MHC) but the association with a given phenotype has been either controversial or inconclusive.

To date the strongest association of a cell marker with rheumatic fever has been the identification of a B cell marker apparently unrelated to the MHC by Patarroyo in Colombia and our group in New York. The relative risk of contracting the disease if one bears the marker was 12.9. Because of the limited supply of the original alloantiserum used to identify the marker, we embarked on a series of studies attempting to reproduce this marker using hybridoma technology and immunization of mice with B cells isolated from rheumatics. Of a number of monoclonal antibodies, we have recently isolated one called D8/17 which identifies all rheumatics tested in a number of widely differing geographic areas of the world. The antibody is also not related to the MHC, and family studies indicate this marker is inherited in an autosomal recessive fashion. The exact nature of the antigen is as yet unknown but our experiments suggest it is not present on other lymphoid cells. The antigen is, however, also expressed on other tissues, most notably the heart and smooth muscle cells. What role this antigen plays in the disease process is unknown at present but its expression on B cells from all rheumatics strongly suggests its direct involvement in the etiopathogenesis of rheumatic fever.

Chagas disease

Although rarely seen in more temperate climates this disease is endemic in many parts of the world, most notably in South America where an estimated 11 million people or more are infected with *Trypanosoma cruzi*. The acute disease is the result of multiplication of the organism in the reticuloendothelial system followed by direct invasion of muscle tissue, liver

and occasionally the meninges. In contrast, in chronic Chagas' cardiomyopathy, the organism is absent but there is a progressive inflammatory cardiac myofibrillar degeneration with necrosis. An important clue to the etiology of the chronic form of disease was provided by Cossio and coworkers who noted that the sera from a high percentage of these patients contained antibodies reactive against components of cardiac sarcolemma as well as with the valvular endothelial cells. A causal role for this antibody in disease pathogenesis was suggested when cardiac biopsies from Chagas patients demonstrated immunoglobulin bound to cardiac myofibers. Eluted antibody from this tissue bound to myofibers of unaffected heart tissue in a pattern similar to that seen in the patient.

In addition to the presence of immunoglobulin in these biopsies, numerous investigators have also commented on the presence of chronic lymphocytic infiltrates in these tissues, suggesting that abnormalities in cellular reactivity might also be involved in the initiation and/or perpetuation of target organ damage. Santos-Buch and colleagues examined cellular immunity in a mouse model of Chagas' disease and noted that sensitized cells from these animals exhibited cytotoxic activity for mouse heart cells in culture. As with rheumatic fever (see above) the addition of heart-reactive antibody from these animals did not enhance the cytotoxicity, again suggesting that cellular autoimmunity to heart antigens might play the primary role in this disease.

As with chorea of rheumatic fever, a new chapter is being written on the relationship of the *T. cruzi* antigens to structures of the parasympathetic nervous system causing the neurological manifestations of the disease. Several investigators have now reported antigenic cross-reactions between *T. cruzi* and neuronal and glial antigens. Using cloning techniques and recombinant technology, Voorhis and Eigen have shown that a 160 kDa *T. cruzi* flagellar protein cross-reacts with a 48 kDa human neuronal antigen. Immunoperoxidase studies of brain sections revealed that at least part of the reaction is related to a neuronal protein of the myenteric plexus (also found in the neurons in the ileum) perhaps explaining the observed megacolon and megaesophagus so often seen in Chagas patients. Interestingly, this cross-reaction was also localized to the Purkinje fibers of the brain.

In summary, autoimmune phenomena have been reported and implicated in the etiology of progressive cardiac damage in both experimentally infected animals and chronic Chagas disease in humans (Cossio and colleagues and Gazzinelli and colleagues). It has been suggested that both changes in the T cell reper-

toire (Miniprio and coworkers) and also molecular mimicry (Van Voorhis and colleagues) might be implicated in the pathogenesis of the autoimmune phenomena seen following *T. cruzi* infection. Yet another intriguing possibility is a chronic immune response to local parasites that may persist in cardiac tissue during the chronic stage of the disease (Jones and coworkers). D'Imperio Lima and colleagues have described persistent B cell activation and immunoglobulin production in the murine model of *T. cruzi* infection, even when injected parasites are no longer detected in the blood. Finnegan and colleagues have reported that autoreactive CD4⁺ T cell clones are capable of polyclonal activation of immunoglobulin production of B cells in both MHC-restricted and non-cognate fashions.

Recently, Freire-de-Lima and colleagues have reported that splenic CD4⁺ T cells from chronically infected mice have markedly enhanced autoreactivity towards normal syngeneic but not allogeneic resting B cells. This suggests that enhanced CD4⁺ T cell autoreactivity can be a potential cause of persistent B cell activation and autoantibody production in chronic Chagas' disease.

Cardiomyopathies

It has long been known that numerous microbes, parasites and viruses can cause acute myocarditis. In these clinical syndromes the organism can be readily demonstrated in the tissues of the individual. In contrast, there is an ill-defined group of cardiomyopathies in which the offending organism that caused the acute inflammation is no longer present, yet the cardiomyopathy continues to progress. These cases are distinguished by the presence of lymphocytic infiltrations and, in a majority of cases, increased titers of heart-reactive antibodies. Among the agents considered to be important causal agents in this group of cardiomyopathies have been the group B coxsackieviruses. These agents frequently cause acute cardiac inflammation in humans, and 10–12% of patients go on to develop a more chronic phase of the disease. Because chronic and progressive myocarditis is restricted to a small number of patients, it has also been suggested that there might be a genetic basis for the disease.

This concept has been greatly strengthened by the elegant work of Rose and his colleagues, working with an animal model of coxsackie B3 virally induced myocarditis. Using genetically different strains of mice, they could induce a chronic myocarditis primarily in H-2 congenic strains bearing an A background (i.e. ACA, ASW) whereas C57BL/10 H-2 mice were resistant. A key finding in these studies was that only those mice with heart-reactive anti-

bodies in their sera went on to develop chronic cardiomyopathy; these antibodies were primarily directed against the cardiac isoform of myosin. A causal role for myosin in the etiology of this cardiomyopathy was shown when injection of myosin alone was able to induce severe immunologically mediated myocarditis in certain genetic strains of mice.

Hoping to demonstrate that myosin and the coxsackie B virus shared common antigen determinants, Rose and colleagues were disappointed in their inability to show that heart-reactive antibodies in their coxsackie B3-induced cardiomyopathy cross-reacted with viral antigens. Saegusa and coworkers however, in preparing a series of different monoclonal antibodies against coxsackie B4 virus identified one which both neutralized the coxsackie B4 virus and also bound to rabbit and mouse heart tissue. An important observation was that this antibody did not bind to human heart tissue, suggesting that both the strain of virus and the myosin of a given species may be crucial for the induction of cardiac disease. Whether or not viruses other than coxsackie B are involved in chronic human cardiomyopathies and whether this progression is on a genetic basis, though unknown at present, is a particularly fertile field for future study.

Postpericardiotomy syndrome

The possible pathogenetic role of heart-reactive antibodies in the postpericardiotomy syndrome (PPS) has been investigated over a number of years by Dr Engle and her colleagues. In both adults and children the syndrome appears 10–14 days after surgery, and is characterized clinically by fever, chest pain, pericardial and plural effusions. Long thought to be related to rheumatic fever, it is clearly a separate syndrome. One common feature, however, is the presence of high-titer heart-reactive antibodies in the sera of patients with these conditions.

An interesting and as yet not entirely explained observation for the induction of postpericardiotomy syndrome is that while the syndrome can be induced by damage to cardiac muscle and the surrounding pericardium, it is almost never seen in operations such as those involving repair of coarctation of the aorta or closure of a patent ductus. Furthermore, the degree of trauma to cardiac muscle often defines the severity of the syndrome. For example, excision of ventricular muscle (such as repair of tetralogy of Fallot) results in the highest incidence of the syndrome.

The question of whether or not a microbe is responsible for the induction of the autoimmunity in this syndrome is unresolved. Engle noted that

approximately 70% of her PPS patients had a rise in antiviral titers to one or more of eight common viruses tested (e.g. coxsackie, megalovirus, adenovirus, etc.). The heightened antibody response to a given virus was not constant however, and seemed to vary with viruses common in the community that year. Preliminary experiments attempting to identify viral presence or isolate whole virus from the excised tissues of these patients have been uniformly unrewarding.

In vitro cytotoxic studies do, however, suggest that the heart-specific antibody in the sera of these patients does play a direct role in the disease pathogenesis. The addition of heart-reactive antibody from these patients to cultured beating heart cells *in vitro* was not cytotoxic, yet caused a marked decrease in contractility. The questions of whether or not susceptibility may be mediated via alleles of the human MHC and the role of sensitized lymphocytes in disease pathogenesis have not been answered.

Significance

It is now clear that many microbes share antigenic determinants not only with other microbes but also with a variety of human tissues. Cross-reactions between streptococci and heart tissue, *E. coli* antigens and colonic antigens, HLA-B27 and shigella antigens, gram-negative bacteria and blood groups are but a few examples of these cross-reactions seen in nature. The majority of these cross-reactions are generally harmless and may serve the purpose of protecting humans against a wide variety of microbes which might be pathogenic. However the combination of the right microbe infecting the genetically susceptible host may result in serious autoimmune consequences.

As indicated above, perhaps the two best examples of microbially induced autoimmune cardiomyopathies are RF and Chagas disease. Here the cross-reactions between host and relevant target organs have been well defined; there is an abnormal host cellular and humoral response to tissue and microbial antigens. Further, in RF, there appears to be a genetic predisposition to the disease. Whether this genetic predisposition allows for breakage of tolerance on the part of the host, an abnormal response to the specific cross-reactive determinant or production of anti-idiotypic antibodies bearing the cross-reactive epitopes is unknown and will require further investigation.

In terms of the immune response of the host, it is becoming increasingly apparent that the cellular response to cross-reactive antigens may play a more significant role in the observed pathological damage

then previously thought. In both rheumatic fever and Chagas disease, T cells are specifically cytotoxic for the target organ and the addition of antibody does not enhance the cytotoxicity, suggesting a more crucial role for cellular immunity in the disease process. Similar studies of experimental models of autoimmune heart disease point to the same conclusion. To date, these studies have not been done in either the PPS syndrome of the idiopathic cardiomyopathies.

In more general terms, what is the significance of heart-reactive antibodies in these disease states? It is well-known that organ-specific antibodies increase with age; appear in a variety of other disease states (e.g. systemic lupus erythematosus, RA) and in many instances do not appear to cause damage. Even for rheumatic fever and Chagas disease, is it a question of the 'chicken or the egg'?

In other words, are these cross-reactive antibodies directly involved in the disease process or are they merely a reflection of prior heart damage and a fortuitous cross-reaction with a given microbe? The evidence in rheumatic fever suggests the latter concept is not true since these heart-reactive antibodies are absorbed by both streptococcal and cardiac antigens while heart-reactive antibodies in PPS are absorbed only by cardiac tissue. Thus in RF the heart-specific antibody appears to relate to the infection whereas in PPS the antibody appears to relate to tissue damage.

Whether or not these heart-reactive antibodies (from whatever origin) play a direct role in the disease process is difficult to ascertain with certainty. They do correlate with the disease state and disappear during convalescence; they are seen in the pathological tissue specimens but they do not apparently kill target organ cells or enhance specific cellular cytotoxicity *in vitro*. Perhaps complement activation and/or other factors are needed *in situ* to produce the observed immunoglobulin staining seen in the lesions of several cardiomyopathies. To our knowledge, these experiments have not been attempted *in vitro*.

What is becoming increasingly clear, not only in cardiac autoimmunity but also in other autoimmune diseases such as rheumatic arthritis, is that cellular activation specific for a given target tissue appears to be important in the pathogenesis of disease. Cytotoxic T cells specific for cardiac myofibers are seen in both rheumatic fever and Chagas' disease, and it is our impression they may be important in the pathogenesis of other cardiomyopathies as well. Obviously, it will be important to define the exact nature of the cross-reactive epitopes recognized by these active cells and their role in causing cytotoxicity to human tissue.
